Abstract - This paper presents the design and performance of a pilot tone-aided 32 QAM modem developed for wireless ISDN applications. The modem is capable of transmitting a gross data rate of 70 kbit/s in a 20 kHz channel spacing. A low complexity receiver has been designed that allows the effects of fading and frequency offset to be removed digitally at a low IF using information extracted from the pilot tone. The design has been fully evaluated in narrowband Rayleigh and Rician fading channels. Computer simulations show that extreme Doppler shifts and frequency offsets have little effect on system performance. The design is suitable for mobile radio as well as fixed applications such as Wireless in the Local Loop (WLL).

I. INTRODUCTION

The growing demand for basic rate ISDN services (64 kbit/s) over the PSTN has jeopardised the future of many wireless networks. The prime aim of every wireless operator is to match the services offered over wired networks. This has lead researchers all over the world to investigate novel ways of squeezing more and more data into band limited radio channels. Among the techniques used to increase throughput, one of the most common solutions is the use of higher level linear modulation schemes that transmit multiple bits per symbol.

When comparing modulation schemes, the QAM family can be shown to offer an excellent compromise between bits per second per hertz and symbol error performance in a noisy channel [1]. However, the very nature of the wireless environment results in gross amplitude and phase distortion that must be accurately compensated in order to successfully receive data using high levels of QAM. Extensive research dating back to the early 1980's produced two famous methods for compensating multiplicative distortion in a narrowband wireless channel. These methods rely on the transmission of a reference signal along with the data. The reference is used in the receiver to estimate the precise nature of the channel's amplitude and phase distortion. The first technique inserts pilot symbols in the information sequence [2], whereas the second technique transmits a continuous pilot tone together with the data spectrum to assist the demodulation process [3].

The modem presented in this paper is based on the Pilot Tone Aided (PTA) concept. A gap is created in the centre

of the information bearing signal spectrum and a pilot tone inserted prior to transmission. At the receiver, the tone is extracted from the received signal and used for the purpose of channel estimation and compensation. PTA can be considered as the frequency dual of Pilot Symbol Aided (PSA) correction. However, both systems have important practical differences [4].

The PTA concept was introduced in 1979 with the first mobile voice implementation published by McGeehan and Bateman [3] in 1984. Promising field trial results together with cheap and widely available DSP devices paved the way for the PTA concept to be applied to data transmission. In the late 1980s, Martin and Bateman [5][6] implemented a 16 QAM PTA data transmission system for operation in multipath fading channels. The proposed system was referred to as Transparent Tone In Band (TTIB) and was capable of transmitting up to 9.6 kbit/s using the V.29 modem standard in a 2.7 kHz channel bandwidth.

The system developed in this paper makes use of the 32 cross QAM constellation. The system achieves a gross data rate of 70 kbit/s in a 20 kHz channel bandwidth. The data rate is in excess of the basic ISDN rate (64 kbit/s) and additional coding or control information could also be sent. A low complexity digital receive architecture is used to accurately estimate and then correct for channel distortion. This method also allows frequency offsets introduced by local oscillator drift to be inherently corrected without the need for additional hardware. A novel low IF approach is used in the receiver to avoid the need for Hilbert transforms in the data extraction procedure. These transforms add significant ripple in the pass-band and while this is acceptable for QPSK, the degradation is too severe for a 32 QAM constellation. This new receive method differs substantially from the conventional approach originally proposed by Martin, Bateman and McGeehan.

II. SYSTEM DESCRIPTION

Figure 1 shows the block diagram for the transmitter. A pilot tone is inserted in the centre of the transmit spectrum by splitting the incoming data into two parallel subbands. Each subband operates at 35 kbit/s with data mapped onto separate 32 cross QAM constellations. This results in a gross 14 kbaud/s (7kbaud/s per subband).

Figure 1: Block diagram for the 32 QAM PTA transmitter

The two subbands are modulated onto an upper intermediate frequency (UIF) and a lower intermediate frequency (LIF) with a gap remaining for the required tone insertion. The gap bandwidth depends on the maximum frequency offset and Doppler shift to be corrected in the system. In this particular system, a gap bandwidth of 700 Hz has been used at a centre frequency of 14 kHz. This choice results in a relaxed specification for the bandlimiting root raised cosine filters with an excess bandwidth factor of 0.38. The low IF signal at the transmitter can be written mathematically as:

$$S_T(t) = A_1(t)\cos(\omega_{UIF}t + \phi_1(t)) + A_2(t)\cos(\omega_{LIF}t + \phi_2(t)) + A_3\cos(\omega_Ft + \phi_3) \quad (1)$$

where $A_1(t)$, $A_2(t)$, A_3 represent the amplitudes, ω_{UIF} , ω_{LIF} , ω_F the frequencies and $\phi_1(t)$, $\phi_2(t)$, ϕ_3 the phases of the upper intermediate subband, lower intermediate subband and pilot tone respectively.

When the signal arrives at the receiver, it is corrupted by amplitude and phase distortion as well as Additive White Gaussian Noise (AWGN). The IF signal at the receiver can be written as:

$$S'_R(t) = A_1(t)A_{ch}(t)\cos(\omega_{UIF}t + \phi_1(t) + \phi_{ch}(t)) + A_2(t)A_{ch}(t)\cos(\omega_{LIF}t + \phi_2(t) + \phi_{ch}(t)) + A_3A_{ch}(t)\cos(\omega_Ft + \phi_3 + \phi_{ch}(t)) + n(t) \quad (2)$$

where $A_{ch}(t)$ and $\phi_{ch}(t)$ represent the amplitude and phase of the distortion introduced by the radio channel and $n(t)$ represents the contribution due to AWGN.

In communication systems, when the received signal is down converted from RF to IF, it is common for local oscillator drift to cause frequency offset in the received

signal. This makes the received signal impossible to detect. Equation 2 can be modified to incorporate the effect of frequency drift as shown below:

$$S_R(t) = A_1(t)A_{ch}(t)\cos(\omega_{UIF}t + \omega_Dt + \phi_1(t) + \phi_{ch}(t)) + A_2(t)A_{ch}(t)\cos(\omega_{LIF}t + \omega_Dt + \phi_2(t) + \phi_{ch}(t)) + A_3A_{ch}(t)\cos(\omega_Ft + \omega_Dt + \phi_3 + \phi_{ch}(t)) + n(t) \quad (3)$$

where ω_D represents the frequency drift (in radians) introduced by the oscillators. In this design, two-stages of frequency correction are used. A *coarse frequency correction* stage is implemented at IF to correct gross frequency errors. After this process, a maximum frequency error of ± 150 Hz remains. A digital baseband *fine frequency correction* procedure has been simulated in this paper to correct this residual error.

Demodulation and detection of the received signal requires accurate compensation for the channel's amplitude and phase distortion. Figure 2 shows the block diagram for the 32 QAM PTA receiver. The pilot tone is extracted by digitally filtering the received signal spectrum at baseband. The channel estimation and compensation block is used to estimate the amplitude and phase distortion from the extracted tone. This information is used to generate pre-distorted upper and lower subband carriers. Each carrier is multiplied with the received signal to automatically translate the subbands to baseband while correcting for local oscillator drifts and radio channel distortion. The baseband signals contain images that are removed by passing them through low pass root raised cosine (RRC) filters before sending the samples for hard decision and 32 QAM demapping. The two 35 kbit/s data streams are finally combined to form the original binary signal.

III. PILOT TONE TO DATA POWER

In the generation of $S_T(t)$, the ratio of the pilot tone power to the data power plays an important role in defining the overall performance of the system. At the receiver, if the pilot tone is buried in noise, it produces a noisy reference that degrades system performance considerably. On the other hand, if the pilot tone power is very high, it reduces the power in the data bands and this makes it difficult for the 32-QAM constellation to be detected. The pilot tone to data power ratio is defined mathematically as:

$$R = 2 A_3^2 / (E[A_1^2(t)] + E[A_2^2(t)]) \quad (4)$$

where $E[\cdot]$ represents the mean or expected value.

In this study, the pilot tone to data ratio has been optimised by performing a simulation in AWGN for the proposed 32-QAM modum. The results are presented in Figures 3a & 3b and show that $R=0.2$ minimises the error rate and hence this value is used in all subsequent simulations and system evaluations.

Figure 3a: BER of 32-QAM in AWGN for different values of pilot to data power ratio

Figure 3b: SER of 32-QAM in AWGN for different values of pilot to data power ratio

IV. PEAK TO MEAN POWER

High pilot tone powers also result in a larger peak-to-mean power ratio at the transmitter and this translates

into greater amplifier linearity requirements and/or back-off levels. The peak-to-mean power ratio for the transmitted signal is defined mathematically as:

$$\eta = \frac{\max\{S_T(t)\}}{E[S_T(t)]} \quad (5)$$

A simulation study has been performed to calculate the ratio η by drawing the cumulative probability for the transmit peak-to-mean power ratio under linear power steps of 0.05 Watts. Figure 4 indicates that the peak-to-mean transmit power is exponentially distributed. The cumulative graph also indicates that for 99.9% of the time the peak-to-mean power ratio remains below a linear value of 8.4 (relative to the mean power). Converting this value into the more usual log form, the 99.9% peak-to-mean value is found to be 9.24 dB. Signal powers above this value should be limited in the transmitter.

Figure 4: Histogram and cumulative count of peak-to-mean transmitted power

V. RAYLEIGH PERFORMANCE

The performance of the system in a Rayleigh fading environment has been evaluated for a range of different Doppler spreads and local oscillator frequency offsets. To generate time correlated Rayleigh fading, an 8-ray model defined by [7] has been used. The In-phase and Quadrature components of this model are defined mathematically as:

$$I_{ch}(t) = \sum_{n=1}^8 A_n \cos(\theta_n + 2\pi f_d t \cos(\alpha_n)) \quad (6)$$

$$Q_{ch}(t) = \sum_{n=1}^8 A_n \sin(\theta_n + 2\pi f_d t \cos(\alpha_n)) \quad (7)$$

where A_n represents the amplitude, α_n the arrival angle and θ_n the phase of n -th ray. f_d represents the maximum Doppler spread. α_n denotes the azimuth arrival angle for the n -th path and is defined as:

$$\alpha_n = \frac{\pi}{4}(n-1) \quad \text{where } n = 1, \dots, 8 \quad (8)$$

θ_n represents the initial phase of each path defined as:

$$\theta_n = 2\pi U \quad (9)$$

where U is a uniformly distributed random variable whose values lie between 0 and 1.

As shown in Figures 5a & 5b, the presence of Doppler can result in an approximate 1 dB degradation in S/N performance. The pilot correction process prevents the generation of an irreducible error floor. The performance of the modem is virtually unaffected at low Doppler spreads. It can be seen that a Signal to Noise Ratio (SNR) of 32 dB per bit is required to achieve an uncoded Bit Error Rate (BER) of 1 in 1000 bits.

The modem design presented here is virtually transparent to IF frequency offsets up to ± 150 Hz and Doppler spreads of ± 25 Hz. A further increase in these values could be achieved but would require the gap bandwidth and tone extraction filters to be redesigned. Large values of gap bandwidth allow more noise to enter the tone extraction filters and thus produce noisier references. This degrades system performance.

In a simulation, it is mathematically intractable to include the effects of channel fading after the transmit IF processing. Since modulation is a linear process, the channel fading can be simulated at baseband prior to IF modulation. While this approach is physically unrealistic, it does not effect system performance.

Figure 5a: BER of 32-QAM in Rayleigh fading for different values of Doppler spread and frequency offsets ($R=0.2$)

Figure 5b: SER of 32-QAM in Rayleigh fading for different values of Doppler spread and frequency offsets ($R=0.2$)

VI. PERFORMANCE IN RICIAN FADING

Many channels have a dominant component and are more accurately characterised using Rician fading statistics. The effect of the Rician K-factor has been evaluated by simulating the modem in a Rician environment.

Rician fading is generated by extending the Rayleigh fading model to include a single dominant multipath. The ratio of the direct or dominant power P_d to the indirect or scattered power P_{id} is simulated by defining the Rician K-factor:

$$K = P_d / P_{id} \quad (10)$$

In practice, this value is often quoted in dB as $10\log K$. It is convenient in simulations to assume that the dominant path arrives at an azimuth angle of zero. This results in a slightly modified In-phase component. The In-phase and Quadrature components for a Rician channel are defined as below:

$$I_{Rch}(t) = \sqrt{K \sum_{n=1}^8 A_n^2 + \sum_{n=1}^8 A_n \cos(\theta_n + 2\pi f_d t \cos(\alpha_n))} \quad (11)$$

$$Q_{Rch}(t) = \sum_{n=1}^8 A_n \sin(\theta_n + 2\pi f_d t \cos(\alpha_n)) \quad (12)$$

Figures 6a and 6b indicate that for low K-factors the performance is close to that of a Rayleigh channel. However, as the value for the K-factor increases, the performance tends towards the AWGN case. For fixed links, the use of directional antennas will tend to result in more Rician channels and therefore an improved performance versus signal to noise.

CONCLUSIONS

In this paper a pilot tone aided 32 QAM modem has been developed offering a basic 64 kbit/s ISDN service (70 kbit/s gross) in a 20 kHz channel. A transceiver design has been produced that automatically corrects for the effects of multiplicative channel fading and local oscillator frequency drifts. The architecture supports simple pilot tone correction using a novel process of pilot detection and pre-distorted subband down-conversion. The design avoids the need for Hilbert transforms in the data extraction path.

The simulation of the 32 QAM PTA modem in AWGN indicates an optimum pilot tone to data power ratio of 0.2. Statistical analysis of the transmitted signal power has shown that the transmit envelope remains below a value of 9.24 dB (relative to the mean) for 99.9% of the time.

A SNR of 32 dB is required to achieve a BER of 10^{-3} in worst case Rayleigh fading conditions. Transmission

through Rician fading improves the required SNR and for the highest values of K factor (i.e a Gaussian channel) the required SNR approaches 14 dB for a BER of 10^{-3} .

The use of pilot tones makes 32 QAM virtually transparent to errors introduced by Doppler and frequency offsets. Given the rigorous performance of the modem in Rayleigh and Rician channel, the design is expected to be suitable for both fixed wireless and mobile radio applications.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Professor Joe McGeehan for his help during the modem development and for the provision of original literature relating to the process of pilot tone correction. This work was funded by Linear Modulation Technology.
