Dear Ernesto L. Schiffrin,

We read with great interest the recent paper by Retnakaran et al.\(^1\) describing an association between higher maternal pre-pregnancy systolic blood pressure and increased probability of delivering a boy. As the authors suggested this finding needs replication, which we aimed to do using the Norwegian HUNT Study.

In the HUNT Study, the entire adult population of Nord-Trøndelag county, Norway has been invited to health surveys since the 1980s.\(^2\) By linking HUNT Study data with the Medical Birth Registry of Norway,\(^3\) which has prospectively recorded all births in Norway since 1967, we identified 2427 women with blood pressure recorded in the HUNT2 (1995-97) or HUNT3 (2006-08) surveys prior to a singleton first pregnancy. Blood pressure was measured at rest by trained staff three times at 1-minute intervals using an automatic oscillometric method (Dinamap, Critikon, Florida). We used the mean of the second and third measurements, or the second measurement for women (n=163) who did not have a third measurement. Associations between pre-first pregnancy systolic blood pressure and sex of the offspring of first pregnancy were analyzed with logistic and linear regression models using Stata. In a very similar fashion to Retnakaran et al. we adjusted for the highest obtained education level, age, current smoking, body mass index, waist circumference, non-fasting serum glucose, high-density and non-high-density lipoprotein cholesterol and triglycerides. We also adjusted for HUNT survey occasion (HUNT2 or HUNT3).

Overall, mean (SD) pre-pregnancy blood pressure among the 2427 women was 121 (11) mm Hg systolic and 70 (9) mm Hg diastolic. There were 1267 (52%) boys and 1160 (48%) girls (sex ratio 1.09). Median time from blood pressure recording to pregnancy was 3 years. Unadjusted pre-pregnancy systolic and diastolic blood pressure was similar before pregnancies with male (121/70 mm Hg) and female (121/70 mm Hg) offspring. The adjusted
differences in pre-pregnancy systolic and diastolic blood pressure between mothers of male
and female offspring were 0.2 mm Hg (95% CI, -0.6 to 1.1) and -0.1 mm Hg (95% CI, -0.8 to
0.5), respectively.

We found no meaningful association of systolic blood pressure with the probability of
male offspring. Overall, each one mm Hg higher systolic blood pressure was associated with
an adjusted odds ratio of male offspring of 1.002 (95% CI, 0.994–1.010). The predicted
probabilities of having a boy by quintiles of systolic blood pressure are shown in Figure 1. As
time from blood pressure measurement to pregnancy was shorter (median: 26.3 weeks) in the
study by Retnakaran et al., we repeated the analysis in a sub-group of females with blood
pressure measurements taken less than 3 years before pregnancy (n=1210); the odds ratio of
having a boy per one mm Hg higher systolic blood pressure was 1.005 (95% CI 0.994–1.015).
Findings were similar for diastolic blood pressure and sex of offspring.

The blood pressure measurement protocol did not substantially differ between our
study and the study by Retnakaran et al. Retnakaran et al. studied a Chinese population whilst
our study population was predominantly Caucasian, included both planned and unintended
pregnancies, and was restricted to first births. However, we do not expect that any causal
effect of maternal blood pressure on offspring sex would differ by these characteristics.

In summary, these results from a Norwegian population-based cohort of greater size
than that of Retnakaran et al., do not support the suggestion that maternal pre-pregnancy
blood pressure influences the probability of delivering a boy.
Yours sincerely,

Eirin B. Haug, Julie Horn, Abigail Fraser, Amanda R. Markovitz, Janet Rich-Edwards,

George Davey Smith, Pål R. Romundstad, Bjørn O. Åsvold
