A Simple Scheme for Enhanced Reassignment of the SPWV Representation of Noisy Signals

Abstract

The reassignment procedure has often been employed to improve readability of some Time-Frequency Representations (TFRs). When processing noisy signals, the problem of sensitivity of the technique to noise is encountered. In this paper, a simple modification of reassignment method is proposed, based on thresholding operation. Specifically, by preventing the reassignment of the distribution coefficients below the noise dependent threshold and replacing them with zeros, the enhanced signatures on the time-frequency plane are obtained. This method is compared with other techniques, such as the Reassigned Spectrogram (RSP) and the Supervised Reassigned Spectrogram (SRSP). An experimental test of these algorithms as the Instantaneous Frequency (IF) estimators for a chirp signal has shown that our method improves the accuracy of the estimation for heavy noise.

1. Introduction

In practical Time-Frequency (T-F) analysis, signals corrupted by noise are commonly encountered, with the additive Gaussian White Noise (GWN) as one possible model of distortion. In such cases, the problem of the TFR’s sensitivity to the presence of noise arise. Previous studies on TFRs of noisy signals considered the kernels for minimum variance representations [1], [9], the robust versions of the Wigner Ville distribution (WV) [8], [5], and the Short Time Fourier Transform (STFT) [5]. In [5], realization of T-F distributions based on the mean and median is presented, with the first solution shown to be suitable for GWN, and the latter for impulse noise. An example of the analysis of the TFRs as IF estimators of noisy signals is presented in [6].

A simple modification of reassignment procedure is introduced in [7], is a non-linear technique which aims to improve resolution in the T-F or Time-Scale (T-S) domain [2]. Although for signal-only sequences the benefits of this method are clear, this technique appears to be highly sensitive to noise and yields sharp peaks in regions where conventional smoothing would flatten the distribution. In [3], a robust technique, the SRSP is proposed: an improvement to the original method, introduced by a multi-window extension of the procedure.

The methods mentioned so far usually required some modifications of the kernel or the use of several kernels during the smoothing process. These modifications may limit the use of "signal matched" kernels designed for extraction of particular features of a signal. The use of more than one smoothing window increases the computational load of the procedure. Also, the choice of an appropriate window combination for a signal with unknown characteristics, or containing components other than FM signals (e.g. T-F atoms, transients), is not trivial.

In some applications the reassignment technique is used to modify the TFR, to improve performance of a feature extraction or classification system. In such cases, the removal of noise and the reduction of the dimensionality of a problem is desirable. As mentioned before, conventional reassignment is sensitive to noise and thus additional refinement technique is required. In this paper, we propose a simple modification of the reassignment procedure by introducing a thresholding operation to the reassignment algorithm itself. This prevents the procedure from reassigned noisy regions of the T-F plane into sharp ridges, while still performing reallocation of the signal component coefficients. This modification can be easily extended to other transforms for which a reassignment procedure exists. The method improves the accuracy of the IF estimation for a noisy signal and has potentially lower computational complexity than other approaches.

2. Method Description

2.1. The SPWV and its reassigned version

All Cohen Class distributions can be written as the double convolution of the WV of the signal and a two-dimensional T-F smoothing function $L$ [4]:

$$TFR_w(t, \omega; L) = WV_w(t, \omega) * * L(t, \omega) = \iint WV_w(t', \omega')L(t-t', \omega-\omega')dt'd\omega' \over 2\pi,$$  (1)

$Cohen$
where $WV_x$ is defined as

$$WV_x(t, \omega) = \int x \left( t + \frac{t'}{2} \right) x^* \left( t - \frac{t'}{2} \right) e^{-i\omega t'} dt'$$

Different TFRs can be obtained from the fundamental WV distribution by applying a different smoothing function $L$. In our experiments a Gaussian separable 2-D function has been used, with the time and frequency widths as parameters. A Gaussian function is used for its optimum T-F localisation property [4]. Here, instead of defining each width separately, we first choose one of the lengths, $a_0$, and adjust the volume of the kernel with parameter $\alpha$, in the spirit of coupled smoothing:

$$L(t, \omega) = g(t)H(\omega) = \frac{1}{\alpha^2} e^{-t^2/\alpha^2} - \omega^2/\beta^2,$$  \hspace{1cm} (2)

where

$$\alpha = a_0^{1/2}, \quad \beta = \frac{\omega}{\alpha_0^2}.$$  \hspace{1cm} (3)

The positive distributions are obtained for $\nu \geq 1$ [4]. In this paper $\nu = 1$ is used, so that the smoothed distribution is equivalent to the Spectrogram (SP). In such cases, $L$ is the WV distribution of the SP smoothing window of width $\sqrt{2a_0}$.

Reassignment consists of shifting coefficients of a representation in the T-F plane using an appropriate prescription for the displacements [2]:

$$RTFR_x(t', \omega'; L) = \int TFR_x(t, \omega) \delta(t' - \hat{t}(t, \omega)) \delta(\omega' - \hat{\omega}(t, \omega)) \frac{d\omega}{2\pi}$$  \hspace{1cm} (4)

Coordinates of the reassignment for the Smooth Pseudo Wigner-Ville distribution (SPWV) are computed with two additional TFRs. Since the WV distribution is smoothed directly in (1), we can 'reuse' the WV and together with two additional smoothing functions,

$$L^1(t, \omega) = tL(t, \omega)$$

$$L^2(t, \omega) = \omega L(t, \omega),$$

substitute them back into (1):

$$TFR_x(t, \omega; L^1) = WV_x(t, \omega) * L^1(t, \omega)$$  \hspace{1cm} (5)

$$TFR_x(t, \omega; L^2) = WV_x(t, \omega) * L^2(t, \omega).$$  \hspace{1cm} (6)

The ratio of resulting distributions is then used to compute the reallocations [2]:

$$\hat{t}(t, \omega) = t - \frac{TFR_x(t, \omega; L^1)}{TFR_x(t, \omega; L)}$$  \hspace{1cm} (7)

$$\hat{\omega}(t, \omega) = \omega + \frac{TFR_x(t, \omega; L^2)}{TFR_x(t, \omega; L)},$$  \hspace{1cm} (8)

2.2. Noise rejection procedure

We consider the signal model

$$x(t_k) = f(t_k) + w(t_k),$$

where both components, a deterministic signal $f(t_k)$, and the noise $w(t_k)$, are analytic. The analytic noise can be written as $w(t_k) = w_r(t_k) + jw_H(t_k)$, where $w_r(t_k)$ is a real GWN noise with variance $\sigma_w^2/2$ and $w_H(t_k)$ is the Hilbert transform of $w_r(t_k)$ [9]. Throughout this paper, $t_k$ and $\omega_k$ will stand for appropriately discretised time and frequency coordinates.

The noise rejection procedure consists of preventing the noisy parts of the distribution from being reassigned and possibly modifying them. Following the discrete algorithm derived in [2], we replace negligible energy thresholding with a decision step. Specifically, having computed T-F distribution $TFR_x(t_k, \omega_k)$, we construct the rejection area $\mathcal{B}$, based on a threshold $\epsilon(t_k, \omega_k)$:

$$\mathcal{B} = \{(t_k, \omega_k) : |TFR_x(t_k, \omega_k)| < \epsilon(t_k, \omega_k)\},$$

and then, at every point on the T-F plane $(t_k, \omega_k)$, we perform one of the two operations on a coefficient $TFR(t_k, \omega_k)$ depending on the pre-defined constraints:

$$RTFR(t_k, \omega_k) = RTFR(t_k, \omega_k) + \alpha(t_k, \omega_k) TFR(t_k, \omega_k)$$

if $(t_k, \omega_k) \in \mathcal{B},$

$$RTFR(t_k, \omega_k) = \alpha(t_k, \omega_k) TFR(t_k, \omega_k)$$

otherwise.

The second operation is a reassignment step. The first operation depends on pre-defined values of $RTFR(t_k, \omega_k)$ and $\alpha(t_k, \omega_k)$. Here, we initialize the $RTFR(t_k, \omega_k)$ to zeros as in [2], and replace the rejected noise coefficients with zeros, i.e.

$$\alpha(t_k, \omega_k) = 0 \quad \text{for} \quad (t_k, \omega_k) \in \mathcal{B}, \quad \text{and}$$

$$\alpha(t_k, \omega_k) = 1 \quad \text{otherwise}.$$

As a result, only coefficients $TFR(t_k, \omega_k)$ above the threshold $\epsilon(t_k, \omega_k)$ will be reassigned, as opposed to the conventional method that reassigns all the coefficients. The area $\mathcal{B}$ may be thought of as a decision map analogous to that of [3], but computed using different criteria and derived from only one realisation of the distribution. Depending on the nature of signal, different estimates of a threshold $\epsilon$ are possible. Here, we assume unknown noise level, and a deterministic nature for the signal. For the purpose of enhancement of the output reassignment representation, a global threshold value $\epsilon(t_k, \omega_k) = \epsilon = \max\{TFR(t_k, \omega_k)\}$ was chosen. Since the representations we have considered are energy distributions and the signals have zero mean, we can expect $\epsilon = \var\{x(t)\} = \var\{|f(t)|^2\} + \sigma_w^2.$ It should be noted that this approach
does not preserve the energy of the noisy signal since some of the samples are set to zero. The potential of a two-dimensional local threshold mask and different values of $a(t_k, \omega_k)$ will be a subject of further investigation.

It is clear that, apart from noise removal, this technique is expected to reduce the number of required operations and computing time, depending on the signal, the extent of the noise regions and the threshold. The number of operations

3. Performance Tests

3.1. IF estimation

For analysis of the developed method as an IF estimator, we have chosen a chirp signal corrupted by additive GWN noise as described in Section 2.2: 

$$x(t) = A e^{i \omega t} + w(t).$$

In this simulation $t = [0, 1]$, with sampling period $T = 1/N$. The number of samples used was $N = 256$. The input SNR is defined as $\text{SNR}_{in} = 10 \log_{10} \frac{A^2}{\sigma^2} \text{dB}$. To avoid discretisation error, the value of $c = N\pi/2$ was chosen so that the IF, $\omega(t) = 2ct$, lies on points of the discrete T-F grid.

The performance was assessed in terms of the mean squared error of the IF estimation, $E\{ (\omega(t) - \hat{\omega}(t))^2 \}$, with the IF estimator

$$\hat{\omega}(t) = \arg\{\max_\omega \{TFR(t, \omega)\}\}.$$

The TFRs used in the comparison were: the WV, the RSP, the SRSP [3], and the developed method implemented as the SPWV with the kernel defined in (5)-(6) (see Fig. 1 for examples of the distributions). Smoothing windows were chosen to give equivalent non-reassigned distributions. The noise sequences with $\text{SNR}_{in} = [-10...10] \text{ dB}$ with 1.25 dB step were added to the test signal and 50 simulations were performed using the TFRs from the set above. The estimation error is shown in Fig. 2. It can be observed that the thresholded reassignment outperforms the conventional RSP and supervised reassignment (SRSP) for the signal with $\text{SNR}_{in} = -10...6.25 \text{ dB}$. For signals with small amount of noise (i.e. $\text{SNR}_{in} > 6.25 \text{ dB}$) the thresholding will cause distortion, which contributes to the error. It should be noted, that the WV is the best estimator, as

![Figure 1. Examples of TFRs of noisy signal (top figure, only real part shown) computed in the simulation ($\text{SNR}_{in} = 0 \text{ dB}$): (a) WV, (b) RSP, (c) SRSP, (d) developed method; $k$ and $l$ are time and frequency coordinates, respectively. For the sake of visualisation, the dynamic range of the images was limited to 20 dB from peak value and the central part of the image ($\frac{N}{2} \times \frac{N}{2}$) was displayed.](image)

![Figure 2. Mean squared error of IF estimation for a chirp signal corrupted by analytic noise. The developed method has been labelled as $\text{RSPWV}_{THR}$](image)
expected for the isolated linear chirp case. It is however known that for other multicomponent signals like, for example, two parallel chirps of finite length, located sufficiently close to each other, the level of cross-components would rule out the WV as the IF estimator using peak value. For example, the estimation error for the signal (mean squared error for the first of the two components):

\[ z(t) = e^{j\omega(t)^2} + e^{j\omega(t+0.125)^2} + w(t) \] and \( \text{SNR}_m = 0 \text{ dB} \) is 0.069 for the WV, whereas for the modified reassignment the error is 0.058.

3.2. Noisy radar signal example

![Figure 3. The reassignment comparison for a noisy signal with unknown characteristic: (a) the conventional method, (b) the developed technique.](image)

Benefits of the thresholding procedure can be more obvious in the case of signals with unknown characteristic. Our aim here was to pre-process automatically representations for subsequent feature extraction. Fig. 3 compares the conventional RSP and modified reassignment representation of a simulated radar return from an unknown object. The SNR for the signal is 7 dB, Peak-SNR is 13.6 dB. The RSP distribution was then thresholded to achieve similar shape of the main lobe of the signal (expected in this radar system in the interval \( k = [97, 160] \)) and the modified representation was left intact. The developed procedure outputs a clearer image, whereas conventional reassignment contains reassigned noise above the threshold and thus it would require further processing.

4. Conclusions

We have proposed a modification of the reassignment method for noisy signals which leads to the enhancement of the output distribution. It has been shown that introducing a thresholding procedure, with the threshold based on a variance of the noisy signal is sufficient to improve the IF estimation for the chirp signal over the conventional method. Further experiments confirmed usefulness of the method for the automated enhancement of T-F images of noisy radar returns. The method is expected to have lower computational complexity than other known reassignment techniques due to re-using the WV matrix and reduction of the number of reallocations in the reassignment procedure.
