The assessment of the allowable bearing load of bored piles ‘floating’ in stiff clay is a standard engineering task. Although the soil mechanics is universal, engineers designing structures in different parts of the world will need to take into account the pertinent codes of practice. It will be helpful to compare such codes, especially in relation to their treatment of uncertainty in the design of bored piles. This paper presents a series of design calculations for a real set of geotechnical data using four international codes of practice: the Australian, American, European and Russian codes. The National Annexes of Ireland, the Netherlands and the UK are used in conjunction with the European code. This selection of countries covers the three Eurocode 7 design approaches (DA1, DA2 and DA3). A non-codified design method is used to provide a base case for comparative purposes with the six codified calculations. A companion paper investigates the issues of soil mechanics in pile design methods, uncertainty in soil parameters and settlement criteria.

Notation

- $A_b$: area of pile base
- $c_u$: undrained shear strength (kPa)
- $D$: pile diameter (m)
- $E_d$: design value of effect of actions
- $f_s$: unit skin friction (kPa)
- $G$: unfactored permanent load
- $I_L$: liquidity index
- $I_P$: plasticity index
- $K$: testing benefit factor
- $L$: length of pile in clay stratum (m)
- $N_c$: bearing capacity factor
- $Q_b$: base resistance of the pile (kN)
- $Q_d$: design load of a bored pile (kN)
- $Q_I$: shaft resistance of the pile (kN)
- $Q_2$: geotechnical design resistance of a pile
- $Q_{work}$: $G + V$ = working load (kN)
- $R_d$: design value of resistance
- $R_{deg}$: design geotechnical strength
- $R_{ULG}$: design ultimate geotechnical strength
- $V$: unfactored variable load
- $z$: depth below top of clay stratum (m)
- $\alpha$: correlation factor between unit skin friction ($f_s$) and undrained shear strength ($c_u$)
- $\beta_1$: partial factor on permanent load
- $\beta_2$: partial factor on variable load
- $\beta_3$: partial factor on $c_u$ along pile shaft
- $\beta_4$: partial factor on $c_u$ at pile base
- $\beta_5$: partial factor on pile shaft resistance
- $\beta_6$: partial factor on pile base resistance
- $\beta_7$: partial factor on design resistance
- $\gamma_{RD}$: model factor used in the UK National Annex to Eurocode 7
- $\varphi_g$: geotechnical reduction factor
- $\varphi_{gb}$: basic geotechnical reduction factor
- $\varphi_{tf}$: intrinsic test factor

1. Introduction

The design of piles in stiff over-consolidated clay is common in geotechnical engineering. The engineer uses judgement, experience, available site data and knowledge of soil mechanics to complete the design task and ensure designs are compliant with the code of practice in force in the relevant jurisdiction. In this paper the requirements of AS2159-2009 in Australia (Standards Australia, 2009), Eurocode 7 (BSI, 2010) in the European Union, the American Association of State Highway and Transportation Officials (AASHTO) load and resistance factor design (LRFD) bridge design specifications (AASHTO, 2007) in the USA and SNiP 2.02.03-85 (SNiP, 1985a) in Russia, are considered together with a simple lump factor of safety design method. The Eurocode
The design example in this paper is a single pile in stiff over-consolidated clay. The data are taken from a site in London. However, this review could equally be applied to other stiff over-consolidated clays such as the Keswick-Hindmarsh Clay of Adelaide, Old Bay Clay of San Francisco, Boom Clay of the Netherlands, Palaeogene Clay of Denmark or Voskresny Clay of Moscow and so on. This problem can be tackled with varying characteristics of the clay, but is generally taken as 9 (e.g. Meyerhof, 1976); and \( u \) is the undrained shear strength (kPa) at the base.

The geotechnical resistance \( (Q_t) \) of a pile is determined using the following equation

\[
Q_t = Q_s + Q_b
\]

### 3. General design formula

Partial factors can be applied at various stages in the calculation process. In limit state design these reflect the different sources of uncertainty. Equation 5 shows the general pile design formula with partial factors, denoted as \( \beta_1 \) to \( \beta_7 \). In the codes of practice reviewed, various combinations of partial factors are used. No one approach utilises all the possible partial factors shown below. Therefore, some will be given a value of unity when the design approach does not specify a value for them. The \( \beta' \) factors shown in Equation 5 all take a value greater than or equal to unity. Equation 5 could be re-written to make the factors less than unity by changing them from multipliers to divisors or vice-versa. As an example, using only one factor (\( \beta_1 \)) with a non-unity value would represent a design approach with a single overall factor of safety.

Since different codes use different terminologies and symbols for various quantities the ‘generic’ notation defined in Equation 5 will be used so that the different approaches can be easily compared. In this paper, the terminology of most recent codes will be adopted, in which the ‘design value’ of a parameter is one that incorporates margins or factors of safety. For an economic design the design load \( Q_t \) equals the design resistance. That is

\[
Q_t = \beta_1 G + \beta_2 V
\]

\[
= \left[ \pi D a \int_0^L \left( \frac{c_u}{\beta_3} \right) dz + A_b N_c \left( \frac{c_u}{\beta_4} \right) \right] \frac{1}{\beta_7}
\]

where \( G \) is the unfactored permanent load; \( V \) is the unfactored variable load; \( \beta_1 \) is the partial factor on permanent load \( (G) \); \( \beta_2 \) is the partial factor on variable load \( (V) \); \( \beta_3 \) is the partial factor on \( c_u \) along pile shaft; \( \beta_4 \) is the partial factor on \( c_u \) at pile base; \( \beta_5 \) is the partial factor on pile shaft resistance; \( \beta_6 \) is the partial factor on pile base resistance; and \( \beta_7 \) is the partial factor on combined shaft and base resistance.
The term ‘partial factor’ is used for the ‘β’ terms to include all types of factors used in the various codes (factor of safety, partial factor, model factor and so on).

In order to compare the different codes fairly a quantity $Q_{\text{work}}$, termed the working load, is defined

6. $Q_{\text{work}} = G + V$

The value of $Q_{\text{work}}$ includes no partial factors and $G$ and $V$ are unfactored loads.

4. Design problem and site data

To illustrate how independently developed codes of practice affect the design of a single pile in clay, as well as the influence that different methods of analysis have on the resulting design, the following example is presented.

An engineer has been asked to determine the allowable working load ($Q_{\text{work}}$, defined as the combined unfactored permanent plus variable load) of the piles shown in Figure 1. In this paper, for simplicity, eccentricity of loading is not considered. The pile to be designed is a bored, straight-shafted, cast-in-place concrete pile, with no load testing carried out on the site. The variable load ($V$) is assumed to be 0.25 times the permanent load ($G$). This is a generic permanent to variable load ratio that has been taken to simulate a standard structure. Information based on Simpson et al. (1980) has been used to provide ground investigation data for the London Clay deposit. Data were collected from six boreholes with locations as shown on Figure 2. The Atterberg limits are summarised in Figure 3. Data from 102 mm unconsolidated, undrained (UU) triaxial tests (Figure 4) and correlated Standard Penetration Test (SPT) data (Figure 5) show the variation of undrained shear strength ($c_u$) with depth in the clay.
To convert the SPT $N_{60}$ values to $c_u$, Equation 7 was used (see Figure 6):

\[
c_u = 4.4(N_{60})^{0.7}
\]

Plasticity index ($I_p$) varies on site from about 30% to 50% (Figure 3). Using the correlation from Figure 6 for $I_p = 30\%$ gives a multiplier on $N_{60}$ for $c_u$ of about 4.7 and for $I_p = 50\%$ a multiplier of 4.2. For an $N_{60}$ equal to 40 the range in $I_p$ values would correspond to a range of $c_u$ from 168 kPa to 188 kPa as $I_p$ decreases. An average $I_p$ of 40% was adopted for the following analysis. Comments on Stroud (1974) with respect to the lack of statistical treatment have been made (Reid and Taylor, 2010). Vardanega and Bolton (2011) showed that a power curve, drawn through Stroud’s data (Figure 6) is a good statistical relationship that could be fitted to the data. The coefficient of determination ($R^2$) of the regression line is 0.37 ($R^2 = 0.37$). The regression curve is similar to Stroud’s original line and the use of either curve results in Equation 7 for a plasticity index of 40%. There is a divergence between the two curves at low and high plasticity indices.

5. **Undrained shear strength ($c_u$) relationship with depth**

Figure 7 shows the combined data from Figures 4 and 5 (converted SPTs and data from 102 mm UU triaxial tests), with linear regression lines through the undrained strength data of individual boreholes. The slope does not vary considerably for the six boreholes. The data points are not highly scattered with
the \( R^2 \) for the individual lines varying from about 0.55 to 0.83. This is not an unexpected characteristic of the London Clay which was deposited in quiet, deep water conditions and has locally had the same geological history of overburden and erosion. Vertical variation is much more likely on this scale, as original deposition conditions change with depth. For instance, locations 50 m apart horizontally (deposited at the same time) may be much more similar than locations 1 m apart vertically (deposited many years apart). Of course, there could be some slight rotation of the bedding, but not very much, and there are occasional anomalies such as faults and pingos.

Regression lines in Table 1 are unsuitable as a design line if they imply negative or unreasonable shear strength at the top of the clay. In a stiff, overconsolidated deposit the mere ability for people to ‘stand on the soil’ implies some shear strength is present. This geological fact means that a blind regression is not advised for the determination of the design \( c_u \) profile. Indeed there is no geological reason for a straight line to be used. The reason for adopting a straight line is that a single gradient can be easily defined, thus simplifying the computation of skin friction.

Many engineers could offer a variety of possible design lines/relationships to characterise the data shown in Figure 7. In this paper, it is assumed that the characteristic value or ‘cautious estimate’ described by the Eurocode is given by Equation 8a. The ‘representative value’ used in conventional design is given by Equation 8b and was derived by an eye fit to the data. Both lines are plotted on Figure 8. Equation 8a is drawn at the 25th percentile (of the total number of data points) parallel to the lower bound trace of the data (also shown of Figure 8). The lower bound trace is used to define the gradient of Equation 8a. This methodology for defining the gradient of the shear strength with depth works because there are no obvious outliers to the lower bound of the data set. The AASHTO and SNiP calculations make use of ‘average value’ soil parameters. In the AASHTO guide, clause 10.4.6.2.2 states ‘correlations for \( c_u \) based on SPT tests should be avoided’. Therefore, for the AASHTO calculations only

<table>

</tbody>
</table>

Table 1. Undrained shear strength relationships for each borehole (coefficient of determination, \( R^2 \), and number of data points, \( n \), used in each regression shown)
the triaxial data were used to characterise the strength increase with depth; this is given by Equation 8c and the line shown on Figure 8. For SNiP, calculations are based on liquidity index and not \( c_u \): 

\[
\begin{align*}
8a. \quad c_u &= 39 + 9.86z \quad \text{(kPa)} \\
8b. \quad c_u &= 40 + 11z \quad \text{(kPa)} \\
8c. \quad c_u &= 24.8 + 13.9z \quad \text{(kPa)}
\end{align*}
\]

The rationale for a line similar to Equation 8a is that it lies below the mean of the data and is a cautious estimate of strength and therefore a good choice for the ‘characteristic value’ that is required for determination of soil properties in Eurocode 7. It is acknowledged that a 5th percentile line could be used, but that this is an extremely conservative view of what is essentially a large amount of data (Simpson et al., 2009).

6. **Conventional design**

For comparison with the codes considered in this paper a simple design method is presented as the base case. The design is based on a global factor of safety.

BS 8004 (clause 7.3.8) (BSI, 1986) states in general, an appropriate factor of safety for a single pile would be between two and three. Low values within this range may be applied where the ultimate bearing capacity has been determined by a sufficient number of loading tests or where they may be justified by local experience; higher values should be used when there is less certainty of the value of the ultimate bearing capacity.

(BS 8004 has now been superseded by BS EN 1997-1:2004).

For the purpose of this example a value of 3.0 is adopted herein assuming that no pile load testing is carried out. For ‘conventional design calculations’ Equation 5 reduces to Equation 9

\[
Q_d = \frac{\beta_1 G + \beta_2 V}{\beta_7} = \sqrt{\frac{\pi Da \left( \frac{c_u}{\beta_3} \right) dz}{\beta_5} + \frac{A_b N_c (c_u/\beta_4)}{\beta_6}}
\]

5.

\[
Q_d = G + V = \sqrt{\left( \frac{\pi Da \left( \frac{c_u}{\beta_3} + A_b N_c c_u \right)}{\beta_6} \right)}
\]

9.

where \( \beta_7 = 3.0 \).

Calculations for a conventional design, for a 15 m long (12 m into the clay), 0.45 m diameter pile follows
For a single pile, not a group, $E_d$ will be taken as the load imparted from the pile cap to the individual pile. The code defines $R_{d,g}$

$$R_{d,g} = \phi_g R_{d,ug}$$

$R_{d,ug}$ is the design ultimate geotechnical strength, determined from site data and calculation methods; $\phi_g$ is the geotechnical reduction factor (not to be confused with friction angle)

$$\phi_{gf} = \phi_{gb} + (\phi_{gt} - \phi_{gb})K \geq \phi_{gb}$$

$\phi_{gt}$ is the intrinsic test factor; $K$ is the testing benefit factor; and $\phi_{gb}$ is the basic geotechnical reduction factor.

In this example no load testing is being considered so $\phi_{gt} = \phi_{gb}$ as calculated in the next section. There is a testing benefit factor ($K$) in the Australian code which allows $\phi_{gb}$ to be reduced if load testing is performed. $K$ is determined using the percentage of piles statically or dynamically tested (see clause 4.3.1 of AS2159-2009).

### 7. AS2159-2009 (Australia)

The Australian approach to designing piles makes use of partial factors with loads being factored separately from the capacities. A single factor is applied to the calculated geotechnical resistance, termed the ‘geotechnical reduction factor’, applied to the calculated resistances, not the soil parameters.

AS2159-2009 (Standards Australia, 2009) directs the engineer to AS/NZS 1170.0 (Standards Australia, 2002) (structural design actions) for the load factors. The two relevant combinations for a pile are most likely to be the greater of: $1.2G + 1.5V$ or $1.35G$. Since, for this design, $V/G = 0.25$, the critical case is $1.2G + 1.5V$. Since this paper is only considering collapse limit states, serviceability and actions induced by ground movements are not considered. Earthquake loading is also not considered.

Clause 4.3.1 of AS2159-2009 states that the design geotechnical strength ($R_{d,g}$) must not be less than the design action effect ($E_d$).

### Table 2. Individual risk rating (after T4.3.2(B) AS2159)

</tr>
</tbody>
</table>
to determine the reduction factor on the geotechnical calculations. It bounds the value of $\phi_{gb}$ between 0.67 and 0.4 for low-redundancy systems and between 0.76 and 0.47 for high-redundancy systems. For low-redundancy problems, this is akin to dividing the calculated resistances by 1.50 for very low risk and 2.5 for very high risk, as shown in the ‘Equivalent $\beta_7$’ column in Table 4; that is, the ‘partial factor’ on the geotechnical resistance is between 1.5 and 2.5 with the loading being considered separately.

### 7.2 Design calculations

For design to AS2159-2009 Equation 5 reduces to Equation 17:

$$Q_d = \beta_1 G + \beta_2 V$$

$$\text{5.} \quad Q_d = \left[ \pi D \alpha \int_0^L \left( \frac{c_u}{\beta_5} \right) dz \right] + \frac{A_b N_c (c_u / \beta_4)}{\beta_6} \right] / \beta_7$$

$$Q_d = \beta_1 G + \beta_2 V = \left( \pi D \alpha \int_0^L c_u dz + A_b N_c c_u \right) / \beta_7 \text{17.}$$

### Table 3. Geotechnical risk factors, weightings and ratings

</table>

Note: The pile design shall include the risk circumstances for each individual risk category and consideration of all of the relevant site and construction factors (AS2159 T4.3.2(A)).
where
\( \beta_1 \), partial factor on permanent load = 1.2 (AS1170) 
\( \beta_2 \), partial factor on variable load = 1.5 (AS1170) 
\( \beta_7 = 1/\phi_g = 1.92 \).

For a 15 m long (12 m into the clay), 0.45 m diameter pile

\[
Q_d = \beta_1 G + \beta_2 V = \left[ \pi D a \int_{0}^{12} (9.86 z + 39) dz \right. \\
\left. + A_b N_c (9.86 \times 12 + 39) \right] / \beta_7
\]

18.

19. \( Q_d = 1.2 G + 1.5 V = (832.6 + 225.2) / 1.92 \)

Taking
\( V = 0.25 G \)
\( G = 349.8 \text{kN} \)
\( V = 87.5 \text{kN} \)
\( Q_{\text{work}} = 437.3 \text{kN} \).
The equivalent overall FOS = (832.6 + 225.2) / 437.3 = 2.42

8. **Introduction to Eurocode 7**

Eurocode 7 (EN 1997-1:2004 (BSI, 2010)) is a limit state code which employs partial factors. After checking the relevant limit states, the designer must ensure that the design value of the effect of actions, \( E_d \) (the design loads) is less than or equal to the design value of the resistance, \( R_d \) (the design capacity)

20. \( E_d \leq R_d \)

For design by calculation, Eurocode 7 presents three design approaches: DA1, DA2 and DA3. Partial factors can be applied to the actions ‘A’ (i.e. the loads), the material properties ‘M’ (e.g. soil strengths) and the resistances ‘R’ (e.g. skin friction). Different design approaches use different combinations of partial factors. In order for the code to be used within a particular country, the national standards body of that country is required to produce a national annex (NA). The NA will specify which design approach(es) is/are permitted for construction in that country, and specifies the values of the partial factors to be used. In order to demonstrate the use of each design approach, three countries have been selected on the basis of their NA choice: the UK for DA1, Ireland for DA2 and the Netherlands for DA3.

9. **EC 7 – design approach 1 (UK national approach)**

9.1 Partial factors
This design approach is the one adopted by the UK NA to Eurocode 7 (BSI, 2007). In this design approach two sets of calculations are performed (DA1-1 and DA1-2), with the partial factors shown in Tables 5 and 6.

9.2 Model factor
Paragraph 2.4.1(8) of Eurocode 7 states: ‘If needed, a modification of the results from the model may be used to ensure that the design calculation is either accurate or errs on the side of safety.’ Paragraph 2.4.1 (9) states

Note: Partial factors on resistances can be reduced with explicit verification of serviceability limit state (not applicable for this example).

Table 6. DA1-2 partial factors used

If the modification of the results makes use of a model factor, it should take account of the range of uncertainty in the results of the method of analysis; any systematic errors known to be associated with the method of analysis.

The UK NA introduces a model factor termed \( \gamma_{\text{mod}} \). In this example it is applied to the calculated shaft and base resistances to account for the fact that the analysis model is empirically based. The UK NA requires a value of 1.4 (which would be reduced to 1.2 if there were load testing). This term is represented in Equation 6 at the \( \beta_7 \) term; for more information on pile design to Eurocode 7 see Bond and Simpson (2010).

### 9.3 Design calculations

For a DA1-1 calculation Equation 5 reduces to Equation 25 and for a DA1-2 calculation Equation 5 reduces to Equation 22, assuming that no load testing is carried out

\[
Q_{\text{d}} = \beta_1 G + \beta_3 V
\]

\[
= \left[ \pi Da \left( c_u/\beta_3 \right) + \frac{A_b N_c (c_u/\beta_4)}{\beta_6} \right] / \beta_7
\]

Equation 5

For the 15 m pile (12 m into the clay) of 0.45 m diameter DA1-1

\[
Q_{\text{d}} = G + 1.3V = \left[ \pi Da \int_0^L c_u dz + \frac{A_b N_c c_u}{2.0} \right] / 1.4
\]

Equation 22

For the 15 m pile (12 m into the clay) of 0.45 m diameter DA1-1

\[
Q_{\text{d}} = 1.35G + 1.5(0.25G) = \left[ \frac{832.6}{1.0} + \frac{225.2}{2.0} \right] / 1.4
\]

Equation 23

For the 15 m pile (12 m into the clay) of 0.45 m diameter DA1-1

\[
Q_{\text{d}} = 1.725G = [832.6 + 225.2]/1.4
\]

Equation 24

\[
G = 438.0 \text{ kN}
\]

\[
V = 109.5 \text{ kN}
\]

\[
Q_{\text{work}} = 547.5 \text{ kN}
\]

The equivalent factor of safety is 1057.8/547.5 = 1.93. DA1-2 (governs)

\[
Q_{\text{d}} = 1.0G + 1.3(0.25G) = \left[ \frac{832.6}{1.0} + \frac{225.2}{2.0} \right] / 1.4
\]

Equation 25

\[
Q_{\text{d}} = 1.325G = (832.6/1.6 + 225.2/2.0)/1.4
\]

Equation 26

\[
G = 341.2 \text{ kN}
\]

\[
V = 85.3 \text{ kN}
\]

\[
Q_{\text{work}} = 426.5 \text{ kN}
\]

The equivalent factor of safety is 1057.8/426.5 = 2.48.

### 10. EC 7 – design approach 2 (Irish national annex)

To demonstrate the use of DA2 for the calculation of pile load carrying capacity, the Irish NA (NSAI, 2005) has been selected. The Irish NA is unique in that it allows for any of the three design approaches to be used for geotechnical works.

#### 10.1 Design parameters

Table 7 presents the parameters to be used for the Irish adoption of DA2.

#### 10.2 Design calculation

Therefore, for DA2 design to the Irish NA Equation 5 reduces to Equation 27
\[ Q_d = \beta_1 G + \beta_2 V \]
\[ = \left[ \frac{\pi D a L}{\beta_5} \left( \frac{c_u}{\beta_3} \right) dz + \frac{A_b N_c (c_u / \beta_4)}{\beta_6} \right] / \beta_7 \]

11.1 Design calculation
For a 15 m long pile (12 m into the clay) with \( \alpha = 0.5 \) and 0-45 m diameter, where \( V = 0.25G \)

\[ G = 348.2 \text{kN} \]
\[ V = 87.1 \text{kN} \]
\[ Q_{work} = 435.3 \text{kN} \]
The equivalent FOS = (1057.8/435.3) = 2.43

12. American Association of State Highway and Transportation Officials (AASHTO)
The AASHTO bridge design specification (4th edition, AASHTO, 2007) specification adopts a limit state approach known in the USA as LRFD. This can be represented as follows

\[ Q_D = \beta_1 G + \beta_2 V \]
\[ = \frac{\pi D a L}{\beta_5} \left( \frac{c_u}{\beta_3} \right) dz + \frac{A_b N_c (c_u / \beta_4)}{\beta_6} \left/ \beta_7 \right. \]

11. EC 7 – design approach 3 (Netherlands national annex)
The Dutch use design approach 3 (NEN, 2007). The partial factors are applied to the soil strength and the base and shaft resistances (\( \beta_5 \) and \( \beta_6 \)).

\[ Q_d = 1.35G + 1.5V \]
\[ = \left( \frac{\pi D x 0.5}{1.1} \right) \left[ \frac{c_u dz}{1.1} + \frac{A_b N_c c_u}{1.1} \right] / 1.75 \]

By way of example, for a 15 m long (12 m into the stiff clay), 0-45 m diameter pile with \( V \) assumed to be 0.25G this reduces to

\[ Q_d = 1.35G + 1.5(0.25G) = \frac{(832.6 - 225.2)}{1.1} / 1.75 \]

\[ G = 318.6 \text{kN} \]
\[ V = 79.6 \text{kN} \]
\[ Q_{work} = 398.2 \text{kN} \]
The equivalent FOS = 1057.8/398.2 = 2.66

12. American Association of State Highway and Transportation Officials (AASHTO)
The AASHTO bridge design specification (4th edition, AASHTO, 2007) specification adopts a limit state approach known in the USA as LRFD. This can be represented as follows

\[ Q_D = \beta_1 G + \beta_2 V \]
\[ = \frac{\pi D a L}{\beta_5} \left( \frac{c_u}{\beta_3} \right) dz + \frac{A_b N_c (c_u / \beta_4)}{\beta_6} \left/ \beta_7 \right. \]
In the example calculation $\alpha = 0.5$. AASHTO suggest a value of $\alpha$ that decreases with $c_u/p_a$ which can be interpreted as an increase with depth. The value of $\alpha$ as suggested by AASHTO is used to compute the AASHTO capacities in the summary in Section 14, Figures 10 and 11.

For a 15 m long (12 m into the stiff clay), 0.45 m diameter pile

$$Q_d = 1.6875G = \frac{917.8 + 274.3}{2.22 + 2.5}/1.25$$

$G = 248.0 \text{ kN}$

$V = 62.0 \text{ kN}$

$Q_{work} = 310.0 \text{ kN}$

The equivalent FOS = (1192.1/310) = 3.85.

If the shaft and base resistances calculated using the 25th percentile of soil data are compared with the factored capacities here then the equivalent FOS = (1057.8/310) = 3.41.

Note 1: The value of $\eta_i$ represents a conventional design, a conventional level of redundancy and a typical structure.

Note 2: The values for $\gamma_i$ are for the Strength I load combination.

Note 3: The value of $\alpha$ is zero for the top 1.52 m (5 ft) and bottom one diameter.

Note 4: The value of $1/\beta_7$ applies to isolated piles.

Note 5: The value of $N_c = 6(1 + 0.2(z/D)) < 9$
13. SNiP (Russian approach)
The Russian design method for pile capacity is outlined in SNiP 2.02.03-85 (SNiP, 1985a). The method of determining bearing capacity is based on relating pile capacity (shaft and end bearing) to liquidity index ($I_L$) for fine-grained soils and to density and grain size for coarse-grained soils. The minimum liquidity index allowed in the SNiP is 0·2 for the skin resistance and 0·0 for the base resistance; these are higher than the site data would suggest (Figure 9), so use of these values will provide a lower bound result. Values for shaft adhesion as a function of liquidity index, taken from Table 2 of SNiP and values for base resistance as a function of liquidity index, taken from Table 7 of SNiP are shown as charts in Figures 13 and 14 in the Appendix.

Bearing capacity of a bored pile can be calculated using Equation 36, for which Table 9 gives a full explanation of the terminology:

$$F_d = \gamma_c (\gamma_d R A + u \gamma_c f \sum f_i h_i)$$

Note:
1. Made ground was not taken into account in calculations.
2. According to Russian standard the design line for $I_L$ is taken as an average for each particular soil layer.
3. It should be noted that coefficient $f_i$ for the shaft capacity is within the limits 0·2–1·0 according to SNiP, therefore consideration of the design line for $I_L$ constant or changing with depth after $I_L$ equals 0·2 is not important and will not have an effect on the design.

Figure 9. Design line through liquidity index data (SNiP calculation) (see Figure 3 for key)
The factored pile resistance should be taken based on the condition

\[ N = \frac{F_d}{\gamma_k} \]

\( \gamma_k \) – factor of safety = 1.4 (see SNiP 2.02.03-85, item 3.10)

For standard buildings the typical partial factors on variable \( (I) \) and permanent loads \( (G) \) are 1.2. (SNiP 2.01.07-85* ‘Loads and effects’, SNiP (1985b)). For SNiP calculations Equation 5 needs to be completely re-written as Equation 38

\[ Q_d = \beta_1 G + \beta_2 V \]

\[ N = \frac{\gamma_c cR A + \gamma_{cf} \sum f_i h_i}{\gamma_k} \]

\[ N = \beta_1 G + \beta_2 V \]

\[ N = 1.2 G + 1.2 V \]

\[ N = 1.2 G + 1.2 (0.25 G) = (222.7 + 645.6) / 1.4 \]

\[ N = 1.5 G = (222.7 + 645.6) / 1.4 \]

\[ G = 413.5 \text{kN} \]

\[ V = 103.3 \text{kN} \]

\[ Q_{\text{work}} = 516.8 \text{kN} \]

The equivalent FOS = (868.3/516.8) = 1.68. The calculated shaft
and base resistances from the ‘Æcu’ method (832.6 kN and 225.2 kN) gives a combined resistance of 1057.8 kN, which is not too dissimilar to the 868.3 kN from the SNiP calculation. The correlations implicit in SNiP seem to give capacities very similar to UK practice.

14. Summary of results

Table 11 summarises calculations for the 0.45 m diameter, 15 m long pile analysed throughout the paper, using the seven design methods. Figure 10 shows the calculated combined unfactored allowable loads for a 0.45 m diameter pile ($Q_{\text{work}}$) for the various design approaches with respect to pile lengths from 10 to 20 m. Figure 11 shows the same for a 0.9 m diameter pile. Figure 12 shows the global factor of safety for the 0.9 m pile. Most codes have a consistent factor of safety; the UK value drops slightly as the pile lengthens, as the base resistance is less significant and it is the base that has the higher partial factor. The DA2 approach (with the reduction for a bored pile) has an increasing factor of safety as the pile lengthens, as only the skin friction is reduced. In all other cases a single FOS value is used over the range of pile lengths studied. Coincidentally, the DA3 calculations and the AS2159 (Australian) calculations basically give the same results in terms of pile length and overall FOS. Therefore the lines on Figures 10–12 are virtually indistinguishable.

a 3.41 if compare capacity with shaft and base resistances calculated using 25th percentile through the undrained shear strength data. (see Figure 8)

Table 11. Summary calculations, 0.45 m diameter; 15 m long pile
15. Discussion and conclusion
The following observations are made based on the study described in the current paper.

(a) The UK (DA1), Netherlands (DA3) and AS2159 calculations give closely similar results (for this design example, using the $\alpha$-method of calculation) with a global FOS of just under 2.5. The Irish DA2 approach gives a slightly higher FOS value. The difference occurs when AASHTO and SNiP are considered. AASHTO is a very conservative code as the factors and the loading and resistance are very high. AASHTO would be even more conservative if the design line...
(Equation 8a) was used instead of Equation 8c. The fact that AASHTO is mainly a bridge code could be why the variable loading factor of 1.75 is very high and why designs are very conservative. The SNiP calculations are significantly less conservative.

(b) Most codes have the flexibility of applying different factors to the shaft and base resistance. The base is generally factored higher as more uncertainty exists in the determination of what the pile is founded in and how much the base is disturbed by construction. The Australian and Russian codes use a single reduction factor applied to the combined resistances.

(c) The Australian code is unique in that the engineer has input into the factor of safety chosen by means of a simple risk analysis approach. This recognises that site conditions dictate the amount of uncertainty in the design to a certain extent and that a ‘one-size-fits-all’ approach can constrain engineering judgement which is crucial for good design. This could also be seen in the Eurocode context as embodied in the use of a ‘cautious estimate’, which is perhaps a more abstract concept that achieves a similar result.

(d) Direct comparison of the allowable working pile resistance, $Q_{\text{work}}$, for each code is obscured by the fact that different estimates of shear strength were used, especially in AASHTO and SNiP where triaxial data only and liquidity index correlations respectively are used to derive a $c_u$ profile and $f_i$ profile respectively.

(e) There is little guidance in any of the design codes on how to construct a design line for the shear strength profile. Some codes specify (or imply) the use of average soil parameters while Eurocode 7 (design by calculation) requires the use of a ‘characteristic design line’ which is a ‘cautious estimate’. Code drafters could adopt a statistical approach (e.g. mean or 5th percentile); however, it is considered that this ignores the causes of ground variability. The use of a ‘cautious estimate’ or similar concept does allow the engineer a degree of flexibility in this respect. If the engineer accepts each data point as equally valid then a design line could be derived statistically. It does seem curious that partial factors can be assigned without knowledge of how conservatively engineers treat their soil data. If average soil values are to be used in design then higher partial factors are needed than if 5th percentile values are used. This is investigated further in the companion paper (Vardanega et al., 2012).

(f) A complication when comparing different codes of practice is that permanent and variable loads are factored differently from code to code. For a fair comparison of codes, the factors on loads (actions) and resistances need to be brought together. The key to success is that there is a clear understanding between structural and geotechnical engineers as to who applies the partial factors on actions.

(g) For bored piles in London Clay ‘$\alpha$’ of 0-5 is generally recommended. The AASHTO approach and the SNiP approach use similar values of shaft resistance. AASHTO has ‘$\alpha$’ of 0-55 dropping gradually as estimates of $c_u$ increase. In other words this code penalises a high $c_u$ value.

(h) In SNiP the factor $\gamma_{cf}$ can be interpreted as similar to the ‘$\alpha$’ concept as it reduces the shear strength of the clay around a bored pile and relates to the method of installation. The use of liquidity index ($I_L$) is not without basis as relationships between $I_L$ and $c_u$ have been discussed (e.g. Muir Wood, 1983). Possibly, the use of $I_L$ in SNiP ‘works’ because it indirectly measures values of $c_u$, which relate to shaft friction.

(i) An interesting feature of the AASHTO approach is that the SPT is not favoured for design; triaxial data are favoured. This is despite SPT data sometimes displaying less scatter than triaxial data (see Figures 4 and 5 and LDSA (2000)).
The major reason SNiP appears unconservative is that the partial factor on resistance (1.4) and the partial factor on actions (1.2) are both relatively low. It is not known if the estimates of skin friction are conservative or not as the source of the data in SNiP Tables 2 and 7 (Figures 11 and 12 in this paper) is unclear. A comparison with $\alpha_c$ values derived suggests that they are high at shallow depth and low at greater depth. Overall for the 12 m pile, there is little difference between the SNiP representative resistance and that derived from the ‘$\alpha$’ method. It would be interesting to know performance statistics for piled foundation systems constructed under the SNiP framework.

Acknowledgements
Thanks must go to the Cambridge Commonwealth Trust and Ove Arup and Partners for providing financial support to the first author. The first author offers thanks to Professor Malcolm Bolton for his supervision. The authors would also like to thank Professor Harry Poulos for providing a draft copy of AS2159-2009 for examination and for his advice on an early draft of the paper.

Appendix – SNiP design charts
For the shaft resistance of piles in clay, cubic equations of the form in Equation 42 were fitted to the data tables from SNiP. The regression coefficients are shown in Table 12 and the plotted functions in Figure 13.

$$f_i = a(I_L)^3 + b(I_L)^2 + c(I_L) + z$$

For the base resistance of piles in clay, linear equations of the form shown below were fitted to the data tables from SNiP. The regression coefficients are shown in Table 13 and the plotted functions in Figure 14.

$$R = A(I_L) + K$$
kPa below the pile tip
