Abstract. The understanding of the nature and behavior of ice sheets in past warm periods is important for constraining the potential impacts of future climate change. The Pliocene warm period (between 3.264 and 3.025 Ma) saw global temperatures similar to those projected for future climates; nevertheless, Pliocene ice locations and extents are still poorly constrained. We present results from the efforts to simulate mid-Pliocene Greenland Ice Sheets by means of the international Pliocene Ice Sheet Modeling Intercomparison Project (PLISMIP). We compare the performance of existing numerical ice sheet models in simulating modern control and mid-Pliocene ice sheets with a suite of sensitivity experiments guided by available proxy records. We quantify equilibrated ice sheet volume on Greenland, identifying a potential range in sea level contributions from warm Pliocene scenarios. A series of statistical measures are performed to quantify the confidence of simulations with focus on inter-model and inter-scenario differences. We find that Pliocene Greenland Ice Sheets are less sensitive to differences in ice sheet model configurations and internal physical quantities than to changes in imposed climate forcing. We conclude that Pliocene ice was most likely to be limited to the highest elevations in eastern and southern Greenland as simulated with the highest confidence and by synthesizing available regional proxies; however, the extent of those ice caps needs to be further constrained by using a range of general circulation model (GCM) climate forcings.

1 Introduction

One of the largest uncertainties in predicting future climate change is associated with the response of the ice sheets. Instrumental records in the vicinity of the Greenland Ice Sheet (GrIS) show anomalous changes in surface temperatures from pre-industrial to modern (Box, 2002). These, along with

Published by Copernicus Publications on behalf of the European Geosciences Union.
Recent satellite data and surface mass balance calculations (Box et al., 2004; Mote, 2007; Rignot et al., 2008; Bhattacharya et al., 2009; van den Broeke et al., 2009; Mernild et al., 2011; Rignot et al., 2011; Shepherd et al., 2012), indicate that high-latitude ice sheet climate environments are particularly sensitive to change and to anthropogenic warming in particular.

Continental ice sheets can respond to imposed forcings on up to multi-millennial timescales, which limits the ability of predicting cryospheric stability based solely on interannual to decadal variability from instrumental records. Recent modeling studies have focused on the long-term response of the GrIS to elevated greenhouse gas levels. Simulations show that under potential anthropogenic warming scenarios, the GrIS will disintegrate within a few thousand years (Berger, 2002; Gregory et al., 2004; Ridley et al., 2005; Vizcaíno et al., 2008; Stone et al., 2010; Huybrechts et al., 2011b; Robinson et al., 2012). Moreover, a hierarchy of models predict significant reductions of grounded ice on Greenland, even if levels are stabilized at modern levels (Loutre, 1995; Huybrechts and de Wolde, 1999; Greve, 2000; Gregory et al., 2004). A direct consequence of complete disintegration will be a global-average sea level rise of about 7 m, as inferred from present-day volumetric calculations (Bamber and Aspinall, 2013) and modeling work (Alley et al., 2005). The potential loss of the ice sheet raises questions regarding the strength of ice sheet hysteresis (see Calov and Ganopolski, 2005; Pollard and DeConto, 2005; Dyke et al., 2011; Robinson et al., 2012; Koenig et al., 2014) and the possibility that the ice sheet will not reform (regrowth potential) once it is lost (Crowley and Baum, 1995; Lunt et al., 2004; Toniello et al., 2004; Ridley et al., 2010; Dowsett et al., 2012; Stone and Lunt, 2013).

Studies of palaeo-variations of GrIS may contribute to the understanding of these issues and the envelope of its behavior in a future warmer climate scenario.

Palaeoclimatic studies of proxy records (NEEM Community Members, 2013) and numerical modeling (Cuffey and Marshall, 2000; Otto-Bliesner et al., 2006; van de Berg et al., 2011; Colville et al., 2011; Helsen et al., 2013; Reyes et al., 2014) of the past few interglacials confirm that GrIS has a large sensitivity to high-latitude warming. The mid-Piacenzian (Dowsett et al., 2010a) or Pliocene warm period (between 3.264 and 3.025 Ma) has been identified as a potential past climate of high commonality to projected future warming (Haywood et al., 2011a), with higher than modern surface temperatures and with boundary conditions and forcings similar to today (e.g., Pagani et al., 2009; Seki et al., 2010). Hence, the Pliocene warm period (henceforth referred to as the Pliocene) is a particularly suitable period to test the sensitivity of the ice sheet in an environment relevant to future global change.

Terrestrial and marine records for the Pliocene exist in the vicinity of Greenland and act as recorders of environmental change for the warmest interglacials and episodes of glaciation during the Pliocene (De Schepper et al., 2014 for an overview). Ice-rafted debris events recorded in nearby sediments in the North Atlantic are indicative of grounded ice on Greenland. Only a few episodic events occur in the early to mid-Pliocene and become more abundant in the late Pliocene to early Pleistocene (Larsen et al., 1994; Wolf-Welling et al., 1996; Jansen et al., 2000; Kleiven et al., 2002; John and Kristensson, 2002; Alley et al., 2010). This is consistent with sea surface temperatures and δ18O reconstructions in the vicinity of Greenland, which suggest that highly variable and reduced Greenland ice cover prevailed in the late Pliocene before more stable and extensive ice sheets were attained in the early Pleistocene (Nielsen and Kuijpers, 1991; Lawrence et al., 2009).

There is considerable disagreement between sea-level high-sand reconstructions for the Pliocene, with estimates from proxy records and isostatic modeling ranging from 5 m to 44 m above modern sea level (e.g., Dowsett et al., 2010a; Siddall et al., 2010 and references therein; Raymo et al., 2011; Raymo and Mitrovica, 2012). Stacks of benthic δ18O (Lisiecki and Raymo, 2005) provide a global measure of cryospheric variability; however, it is challenging to disentangle Greenland and Antarctic ice sheet fluctuations. Due to the light isotopic signature, in combination with the limited volume changes of the Greenland Ice Sheet the signal is hard to be inferred from the δ18O global stack.

More detailed aspects such as the locations of individual ice centers on Pliocene Greenland require climate and ice sheet modeling. A few modeling studies have attempted to simulate the Greenland Ice Sheet during the mid- to late Pliocene (Lunt et al., 2008, 2009; Hill, 2009; Dolan et al., 2011; Koenig et al., 2011; Solgaard et al., 2011; Koenig et al., 2014). However, assessment of these results has been hindered by the use of disparate initial and boundary conditions and prescribed external forcing.

Global data sets of proxy reconstructions for the Pliocene have recently been established (PRISM3D, Dowsett et al., 2010a, b) providing an excellent framework for modeling studies. A consistent data-driven modeling approach can help to compare models and the sensitivity of ice sheets in the Pliocene leading to a better understanding of long-term future ice sheet response.

This paper aims to reconstruct the location and amount of grounded ice on Pliocene Greenland by means of an ice sheet model intercomparison project (PLISIMIP, Dolan et al., 2012). We apply a data-driven experimental design to provide a better understanding of the dynamics involved in Greenland’s climatic and ice sheet variability. The specific objectives are to identify the uncertainties in sea level contribution due to ice sheet model differences, estimate the potential range in GrIS reconstructions of the Pliocene warm interval, and to quantify the impact of prescribing different ice sheet reconstructions in a climate model. A companion paper will follow, which, in combination with this study, will assess climate model dependency of ice sheet simulations over Greenland for the same time period (Dolan et al., 2015).
The second climatology is from another HadAM3 GCM sen-
experiment using PRISM3 Pliocene boundary conditions 
The first climatology is from the main PlioMIP HadAM3 
simulations of Pliocene Greenland (Pliocene Phase, Fig. 1). 

2 Methods

A set of forcing climatologies and initial conditions are ap-
plied to simulate Greenland’s mass balance in the Pliocene 
relative to pre-industrial/modern. We first describe the ex-
perimental design, followed by model-specific details in 
Sect. 2.1.2.

2.1 Experimental design

Dolan et al. (2012) provide an overview of PLiocene Ice 
Sheet Modeling Intercomparison Project (PLISMIP) and 
describes its experimental design, but important details will 
be reiterated here for convenience. The Control Phase of 
this project aims at testing individual ice sheet model per-
formances under present-day forcings, whereas the Pliocene 
Phase is designed to span an envelope of potential Pliocene 
scenarios by applying a range of climate forcings, and 

ice sheet model starting conditions on Greenland (Table 1, 
Fig. 1).

2.1.1 Forcing

In the first set of experiments (Control Phase), the ice sheet 
models (ISMs) are initialized with model-specific present-
day ice sheets, and driven by climatologies either from a 
HadAM3 pre-industrial control run or from the independ-
ent NCEP/DOE AMIP-II re-analysis data set (hereafter 
NCEP2, Kanamitsu et al., 2002). These tests identify model-
dependent biases when simulating present-day (or equiva-
lent) Greenland Ice Sheets using a single general circulation 
model (GCM) relevant for the inter-model interpretation of 
palaeo-experiments.

Two HadAM3 GCM climatologies are used to drive ISM 
simulations of Pliocene Greenland (Pliocene Phase, Fig. 1). 
The first climatology is from the main PloMIP HadAM3 
experiment using PRISM3 Pliocene boundary conditions 
(Hadprism, see Dowsett et al., 2010a; Haywood et al., 2010). 
The second climatology is from another HadAM3 GCM sen-
sitivity experiment using the same PRISM3 boundary con-
ditions except for isostatically adjusted ice-free Greenland 
topography (Hadpio,gris). The latter scenario is added to 
quantify the uncertainties in simulating the maximum sea 
level contributions by imposing a significant ice mass in the 
Pliocene climatology used to force the ice sheet models. The 
initial Greenland Ice Sheet state for the ISM simulations is 
either that provided by Hill (2009) (PRISM3 GrIS, see 
Dolan et al., 2011) or ISM-specific ice-free rebounded topo-
graphies.

There are various methods that account for temporal and 
spatial mismatches in scale between GCMs and ice sheet 
models (see Pollard, 2010 for an overview). Here, we avoid 
problems associated with the temporal mismatch by consid-
ering the equilibrated ice sheet response to a given climate, 
rather than the transient behavior, i.e., Control and Pliocene 
GCM climatologies are used to drive individual ISMs to an 
equilibrated response. The spatial mismatch is accounted for 
as described below.

Monthly and annual mean temperatures and precipitation 
fields from the GCM and re-analysis data set are re-gridded 
to the required ISM resolution using the interpolation method 
specific to each ISM (see Sect. 2.1.2 and references therein). 
To account for the high-resolution ISM orography compared 
to the coarser GCM and re-analysis grids, a uniform lapse 
rate correction is applied with a value of 8 °C km⁻¹ (Thomp-
son and Pollard, 1997). First, the GCM/re-analysis topog-
raphy and surface air temperatures are horizontally interpo-
lated to the ISM grid, and then the temperature is corrected 
vertically to the ISM surface by \( T - \gamma \times (Z_{\text{GCM}} - Z_{\text{ISM}}) \), 
where \( T \) is the GCM/re-analysis surface air temperature, 
\( z_{\text{ISM}} \) elevation of the ice sheet model, \( z_{\text{GCM}} \) is the GCM/re-
alysis surface elevation, and \( \gamma \) is the lapse rate. Each ISM 
simulation is run for 30 kyr, and extended to equilibrium if 
necessary in 10 kyr increments until the relative change in 
total ice volume per 1000 years falls below 0.01 %.

2.1.2 Ice sheet models

Table 3 provides an overview of ice sheet models applied in 
the experiments. The specifics of each ice sheet model that 
are relevant for the PLISMIP experiments, i.e., ISM resolu-
tion, mass balance calculation, geothermal heat flux, bedrock 
response model, and further model details are available in 

the respective references (ANICE, de Boer et al., 2013; BA-
SIM, Hill, 2009; Dolan et al., 2011; Glimmer, Ruttl et al., 
2009; GRISLI, Ritz and Rommelære, 2001; Peyaud et al., 
2007; IcIES, Saito, 2002; Saito and Abe-Ouchi, 2004; PSUI, 
Polland and DeConto, 2007, 2012). Apart from Glimmer, all 
ISMs are run in absolute mode, i.e., forced with absolute cli-
matologies rather than using an anomaly method that com-
bines climatological anomalies with a control climate (see, 
e.g., Lunt et al., 2008).

Table 1. Experiments for PLISMIP follow Control and Pliocene 
Phases. Forcing climatologies are from HadAM3 GCM control and 
NCEP re-analysis data (see Sect. 2.1). ISM simulations are initiated 
with modern, PRISM3 ice sheet configurations (Hill, 2009) and ice-
free conditions with respective topographies. The ice-free scenarios 
use isostatically rebounded topography on Greenland.

3 Results

Initially we test the performance of ice sheet models in simulating present-day (or pre-industrial) ice sheets forced with GCM and re-analysis data, respectively (Sects. 3.1, 3.2). We analyze Pliocene scenarios both spatially and temporally (Sect. 3.3.1) before quantifying the variability (i) among ice sheet models and (ii) between climate scenarios through sets of statistical measures (Sect. 3.3.2).

3.1 Ice sheet model forcing

Absolute mean annual surface temperatures in modern control simulations from the HadAM3 GCM (Had\textsubscript{ctrl}) are below freezing over all of Greenland with minimum values of $-28$ °C centered over the highest altitudes (Fig. 1a). Precipitation follows the spatial pattern of temperature with relatively low values over much of Greenland except in regions of southern Greenland where moisture transport from the North Atlantic increases precipitation to $> 1$ m yr$^{-1}$ (Fig. 1b). In comparison, annual surface temperatures and
precipitation values from NCEP2 re-analysis (NCEP2_{ctrl}) are warmer by 5–7°C and slightly wetter (Fig. 1c–d). For the Pliocene Phase, both driving climates (Had_{prism}, Had_{plio.nogris}) show temperature anomalies with respect to modern of +15°C up to +23°C in regions where ice sheet reconstructions between Pliocene and modern deviate and elevation and ice–albedo feedbacks are maximized (see Dolan et al., 2012) (Fig. 1e). An additional increase in surface temperatures of 5–8°C is simulated in response to ice-free conditions in the Pliocene GCM scenario Had_{plio.nogris} when compared to the Pliocene scenario Had_{prism}. Slightly higher elevations of the ice-free rebounded topography result in wetter (0.6–1 m yr⁻¹) and slightly colder surface temperatures (∼1–2°C) in southern Greenland (Fig. 1g–h).

3.2 Modern control Greenland Ice Sheet

Bamber et al. (2001a) used airborne laser altimeter data and cartographic data sets to reconstruct a digital elevation data set for Greenland. Ice thickness data is combined with the digital elevation model of Bamber et al. (2001b) resulting in an estimated volume of 2.931 × 10⁶ km³ for the present-day ice sheet. Calculations using Bamber et al. (2001b) data estimate the area to 1.67 × 10⁶ km² (unpublished work, Byrd Polar Research Center). Equilibrated ice sheet model simulations using control GCM (Had_{ctrl}) and NCEP2_{ctrl} forcings compare favorably with volumetric and areal estimates for modern GrIS (Table 2, Control_{ncep}, not shown). Here we assume that ISMs forced with a pre-industrial simulation will reproduce an ice sheet configuration comparable to the present day. The total of all ISMs averages to 3.42 ± 0.47 × 10⁶ km³ for volume and to 2.03 ± 0.26 × 10⁶ km² for areal ice sheet extent, overestimating volume by 18%, and area by 21%. When forced with the HadAM3 climate, Glimmer produces an ice sheet which extends into the modern ocean in the southeast, resulting in a large ice area. The GRISLI ISM significantly overestimates volume, which has consequences for the multi-model average (Table 2).

Figure 2 shows grid-cell elevation differences between simulated control scenarios (Control_{had}, Control_{ncep}) and modern-day observed ice sheets from Bamber et al. (2001a). Both control scenarios lead to comparable present-day ice volumes and extents relative to observations. In addition, modeled ice sheets forced by the GCM climatology Had_{ctrl} do not significantly differ from the ones forced by re-analysis data (NCEP2_{ctrl}). The majority of ISMs simulate present-day GrIS with overall lower elevations (< 250 m) in the center when compared to measurements (with the exception of GRISLI). Ice margins are generally overestimated accounting for the deviations in Table 2. Elevation changes in southwestern, eastern, and northeastern Greenland amount to > 1000 m at the ice margins, a feature uniformly seen in almost all ISMs.

Figure 2. Ice sheet surface elevation [m] anomalies for Control_{had} (left panels) and Control_{ncep} (right panels) relative to observed present-day Greenland Ice Sheet calculations from Bamber et al. (2001a) for individual ice sheet models ANICE, BASISM, Glimmer, GRISLI, IcIES, and PSUI (from top to bottom). Modern-day coastlines are used, and the ocean is masked out for plotting the anomalies.

3.3 Pliocene Greenland Ice Sheet

3.3.1 Evolution and equilibrated ice sheets

In Fig. 3 the temporal evolution of modeled ice volume is expressed as sea level equivalent meters for runs Plio_{prism.icefree}, Plio_{prism}, and Plio_{nogris.icefree}. Equilibrium is effectively reached for most of the runs and scenarios at year
Figure 3. Evolution of ice sheet volumes expressed in sea level equivalent meters [m] for Pliocene scenarios (a) Plio$_\text{prism.icefree}$, (b) Plio$_\text{prism}$, and (c) Plio$_\text{nogris.icefree}$ for individual ice sheet models. Observed present-day values from Bamber et al. (2001a) are indicated for reference. Note changes in integration lengths for scenarios (x axis).

Figure 4. Ice sheet surface elevation [m] for Pliocene scenarios Plio$_\text{prism.icefree}$ (left panels), Plio$_\text{prism}$ (middle panels), and Plio$_\text{nogris.icefree}$ (right panels) for individual ice sheet models ANICE, BASISM, Glimmer, GRISLI, IcIES, and PSUI (from top to bottom).

30 k (see Sect. 2.1) although ISMs require a longer integration time to equilibrate to the Plio$_\text{prism.icefree}$ scenario due to larger deviations between forcing climatology and initial ice sheet model configuration on Greenland. Ice volumes for BASISM scenarios Plio$_\text{prism.icefree}$ and Plio$_\text{prism}$ and IcIES Plio$_\text{prism.icefree}$ do not come into equilibrium and remain oscillating between a stable maximum and minimum due to bedrock and ice interactions. In these instances, the median volume of a full cycle near the end of the run is selected as representative of ISMs’ end state. Except the reconstructions from GRISLI, all Pliocene scenarios lead to volumes that are below modern estimates. The range of modeled volumes from Plio$_\text{prism.icefree}$ and Plio$_\text{prism}$ are within sea level equivalent meters of 4.2–7.6 m and stand in contrast to the scenario Plio$_\text{nogris.icefree}$ with values between 0.8 and 1.7 m.

Although Pliocene simulations result in equilibrated ice sheets significantly smaller in comparison to modern, ice sheet location, extent, and volumes differ considerably be-
SSA is shallow shelf approximation, PDD is positive degree-day scheme, fd is finite difference.

Sample standard deviation (SSD) is a measure of the magnitude of a varying quantity. Here, it refers to the difference in the magnitude of simulated ice sheet thickness between the model (i) and the multi-model mean and is calculated at each grid point by

\[
SSD = \sqrt{\frac{x_1^2 + x_2^2 + \ldots + x_n^2}{n-1}},
\]

where \(x_i\) is the difference between simulated ice sheet thickness in model (i) and the multi-model mean and \(n\) is the number of models. Where SSD is low, the difference in simulated thicknesses between the ISMs is small and vice versa.

It can be interpreted as the differences in the dynamics of the ice sheet models in these regions (Fig. 5a–c). SSD values are \(> 1500\) m in northeastern and southern-central Greenland in both PRISM3d scenarios Pliocene and Plioериcefree, whereas the ice sheet dome region in eastern Greenland shows a low variability. Highest SSD values (\(> 2000\)) are calculated in southern regions for the Pliernesigalikecefree scenario. Other regions show generally low SSD values of \(< 800\) m in variability.

When considered alongside the SSD plots, the ice sheet presence (Fig. 5d–f) suggests areas of Greenland that might be strongly affected by how each individual ISM calculates melting (see representation of ice dynamics). While higher values show regions where the majority of ISMs predict ice of any thickness, lower values indicate a reduced likelihood of ice presence for each particular scenario and correlates to regions of higher SSD values. Although in general ice sheet configurations are a balance between accumulation and melting, in these experiments the areal extent of the ice sheets is largely governed by how much melting is simulated in the ice sheet model; therefore, inconsistencies in ice area may be ascribed to differences in the ISMs melt schemes. There are differences in the details of the predictions between the two experiments Plioериcefree and Plicrism. Nevertheless, 100% of the models agree on the presence of large areas of ice over central and eastern Greenland, with 83% of the mod-

between Pliocene forcing scenarios (Fig. 4). Both Pliocene ice sheet scenarios forced with GCM forcing using PRISM3 boundary conditions (Hadprism) are more extensive than the scenario forced with Hadnogris. The latter forcing climatology has relatively higher surface temperatures over locations where ice reconstructions deviate (see Fig. 1). Forced with the same climatological means but different starting conditions, results from scenarios Ploiperism and Plioериcefree deviate by only 9% in volume and 9% in extent. However, the average volume or area for the Ploinericefree reconstructions correspond to a reduction of 19 and 36% relative to the latter two scenarios (see also Sect. 3.3.3).

3.3.2 Inter-model and inter-scenario analysis

Sample standard deviation (SSD) is a measure of the magnitude of a varying quantity. Here, it refers to the difference in the magnitude of simulated ice sheet thickness between the ice sheet models. SSD is calculated at each grid point by

\[
SSD = \sqrt{\frac{x_1^2 + x_2^2 + \ldots + x_n^2}{n-1}},
\]

where \(x_i\) is the difference between simulated ice sheet thickness in model (i) and the multi-model mean and \(n\) is the number of models. Where SSD is low, the difference in simulated thicknesses between the ISMs is small and vice versa.
Figure 5. Measures of (a–c) sample standard deviation (SSD) and (d–f) ice sheet presence for scenarios Plio\textsubscript{prism, icefree} (left panels), Plio\textsubscript{prism} (middle panels), and Plio\textsubscript{nogris, icefree} (right panels). See text for calculations.

els predicting ice presence over areas in south Greenland. In scenario Plio\textsubscript{nogris, icefree}, ISMs agree on the existence of limited ice caps at eastern and southern high altitudes (100 %) and deviate by 20–40 % of how extensive the ice sheets are in those areas.

Figure 6 synthesizes the results from the model intercomparison. For Fig. 6a we define $C$ as the confidence in reconstruction of ice presence at each grid point given a particular climatological forcing (inter-model confidence, where $k_i$ is the number of models which have ice present in each scenario (i)). The total number of scenarios is defined by $j$, and $n$ is the total number of models (i.e., 6). Calculations are normalized to values 0–1. For Fig. 6a, confidence is highest (1) when all models either agree on ice presence or absence in a particular grid square. Where half the models predict one result and the other half predict the opposite, confidence is low in the ice reconstruction ($C = 0$).

$$C = \frac{2}{j \cdot n} \sum_{i=1}^{j} |k_i - \frac{n}{2}|$$

High $C (> 0.6–1)$ is obtained for an extensive area of Greenland with highest values in central and eastern regions of Greenland. Lower inter-model confidence is obtained in areas in southern Greenland with $C$ between 0.25 and 0.6. In addition, we calculate the overall likelihood of ice presence in a grid square during the Pliocene given the scenarios we have tested. We calculate the sum of ice presence through all of the Pliocene ISM simulations (normalized to 0–1; Fig. 6b). In this case confidence is highest ($C = 1$) where all ISMs in each of the three Pliocene climate scenarios predict ice presence. We find the highest probability of ice presence in eastern high-altitude regions in agreement with high confidence $C$ simulated in those areas (see Fig. 6a). Ice is also reconstructed to be present in southern Greenland, although with slightly less agreement between ISMs.

3.3.3 Relative sea level contributions in the Pliocene

Pliocene ice sheet simulations are analyzed relative to modern observed areal extent, volume, and sea level equivalent height (Bamber et al., 2001a) in Fig. 7. In general, there is a correlation between relative changes in ice sheet volume and the equivalent change in areal extent. Relative changes of both Pliocene scenarios forced with GCM climatology (Had\textsubscript{prism}) group generally feature low within-group variability, i.e., areally between 0.25 and $0.98 \times 10^6$ km$^2$, and between $0.4$ and $1.3 \times 10^6$ km$^3$ in volume. Scenario Plio\textsubscript{prism, icefree} leads to slightly higher reductions in volume and area compared to Plio\textsubscript{prism}. Significant losses are simulated for scenario Plio\textsubscript{nogris, icefree} relative to modern, both areally and in terms of volume, corresponding to a sea level equivalent change of $\sim 6.1$ m with respect to Bamber et al. (2001b) and when considering all ISMs. In summary, relative changes invoked by differing (ice sheet) boundary con-
4 Discussion

We test ice sheet model performances under present-day conditions before intercomparing simulations from palaeo-scenarios (Sect. 3.2). We find that there are no systematic biases introduced when using HadAM3 GCM climatology relative to control experiments forced with NCEP2 re-analysis data. In general, ice sheet models compare favorably to observations, solely ice margins, and hence ice volume, are overestimated, a feature present in all ISMs. This can be attributed to problems in capturing the dynamic marginal ablation zones (see, e.g., Hindmarsh, 1993; Ritz et al., 1996). In turn, estimates of volume, extent, and sea level stemming from observations may not be in equilibrium with the present climate, adding to the observed discrepancies between simulated ice sheets and present-day estimates (Fig. 1).

The three ice sheet model scenarios for the Pliocene warm period presented here are designed to assess the envelope of ice sheet presence on Greenland. Scenarios Plio\textsubscript{prism} and Plio\textsubscript{prism,icefree} lead to relatively extensive ice sheets due to a GCM forcing that mirrors prescribed ice sheets on Greenland (compare to original PRISM3 ice sheet reconstruction, Haywood et al., 2010). In turn, ISM results for scenario Plio\textsubscript{nogris,icefree} equilibrate to ice caps that are limited to the nucleation centers at high elevations in eastern and southern Greenland as a result of higher surface temperatures of an ice-free topography. Proxy records of terrestrial and oceanic origin (see Sect. 1) reconstruct a Pliocene Greenland similar to a projected future Greenland with very limited ice cover (see, e.g., Ridley et al., 2005; Huybrechts et al., 2011a). Reconstructions of palaeo-vegetation for the Pliocene agree, in particular, on ice-free conditions in northern and northeastern Greenland, and regions in southern Greenland (e.g., Csank et al., 2011). We conclude that ice presence was most likely limited to the eastern and southern high altitudes resembling scenario Plio\textsubscript{nogris,icefree}, as simulated with highest confidence (Fig. 6), and in agreement with proxies.

Equilibrated ice sheet volumes and extents are a result and combination of initial ice sheet model configurations (boundary conditions), ice sheet default parameters and physical constants (Ritz et al., 1996; Rutt et al., 2009), and forcing climatologies. Model results show that Pliocene scenarios forced with the same GCM climatology are comparable, independent of the ice sheet model used. In turn, the Pliocene GCM forcing with altered boundary conditions on Greenland lead to significantly different and relatively smaller ice sheets. Thus, starting ice sheet model configurations on Greenland are found to be of secondary importance in contrast to the uncertainties introduced by a change in the (ice sheet) boundary conditions in the GCM. Although internal ISM-specific parameters have been shown to be critical in ice sheet simulations under similar forcing conditions (see Stone et al., 2010 for an overview), by using state-of-the-art ISMs run in their standard mode, our results point to less ice sheet model dependent results. The ISMs respond very similarly to a certain forcing over large areas of Greenland (see Sect. 3.3.2). As a result, alterations in the GCM boundary conditions have the potential to produce the greatest uncertainty in Pliocene ice sheet modeling.

The results presented here are of importance not just regarding ISM dependency, but they also provide a potential alternative to the PRISM3 ice sheet reconstructions when moving forward with PlioMIP Phase 2. Figure 7 displays ice sheet volumes derived from creating a multi-model mean (MMM) for each Pliocene scenario. It is possible that a MMM reconstruction across all the scenarios presented here...
would be more appropriate for future iterations of PlioMIP than simply relying on one ISM, however there will be difficulties in creating a spatially consistent MMM GrIS. Although the creation of a MMM may be fruitful, it is considered premature at present given the results presented here, which suggest that climatological forcing is more important than ISM dependency. It therefore follows that the climate model used to provide the climatological forcing could have a large impact on the simulated ice sheets. Dolan et al. (2015) are currently assessing the degree to which climate model dependency affects Pliocene ice sheet simulations and provides a useful companion to this paper.

5 Conclusions

PLISMIP was initiated in order to address the degree to which ice sheet reconstructions for the Pliocene are dependent on the choice of ISM (Dolan et al., 2012). We show that the degree of ISM dependency is relatively low and in fact the climatological forcing or the boundary conditions applied in the original climate model simulation are of higher importance in terms of the predicted Pliocene ice sheet. We also present the most likely locations of Pliocene ice on Greenland by means of intercomparing model results from six ISMs and forcing conditions. We find that less ice sheet model dependent results require forcings from various GCM scenarios with the same boundary conditions (Haywood et al., 2010, 2011b) to further constrain uncertainties in simulating ice on Pliocene Greenland. Moreover, given Greenland’s sensitivity to imposed forcing, we are in need of proxies on and in the proximity of Greenland to (i) help better constrain model starting conditions and (ii) improve the verification of ice sheet model results.
