Abstract

Background. Chronic hepatitis B virus (HBV) frequently causes liver disease, and early identification can improve outcome. The burden of chronic HBV infection in many economically developed nations lies in migrant populations. Targeted HBV testing of migrants, and contact tracing for those diagnosed, are public health objectives, but uptake has been fragmentary. This qualitative study aimed to investigate understanding of hepatitis B and response to testing and contact tracing amongst people of Somali ethnicity living in Bristol, UK.

Methods. The views of 30 people of Somali ethnicity living in Bristol were explored through focus groups and semi-structured interviews. Transcripts of audio-recorded interviews and focus groups were imported into NVivo10 and inductive thematic analysis undertaken.

Results. Most participants lacked awareness of hepatitis B, and often co-identified hepatitis B with ‘jaundice’. There were frequent misconceptions regarding transmission, natural history and diagnosis, with hepatitis B commonly viewed as a relatively trivial, short lived, symptomatic disease. Hepatitis B was generally not stigmatised. Lack of understanding of the disease was cited as the major barrier to targeted testing and contact tracing.

Conclusion. These findings suggest public health initiatives to promote hepatitis B testing and contact tracing within migrant Somali populations should focus on improving hepatitis B understanding, particularly its natural history and diagnosis, and avoid translation of ‘hepatitis B’ into terms meaning ‘jaundice’ to address misperception of low susceptibility and low severity.

Keywords: hepatitis B; screening; contact; Africa; qualitative; migrant
Introduction

Chronic hepatitis B virus (HBV) infection frequently causes cirrhosis and liver cancer. Early diagnosis can improve outcome through hepatocellular carcinoma (HCC) surveillance and antiviral therapy. HCC surveillance increases survival (1, 2), while antiviral therapy improves surrogate markers of disease progression and is expected to demonstrate improved survival (3). In addition early diagnosis can prevent onward transmission through vaccination of contacts (4).

In many developed nations, including the UK, the burden of chronic HBV infection lies within migrant communities, and screening of migrants for HBV is recommended (5-9). The cost effectiveness of HBV screening depends on adequate uptake of testing and engagement with monitoring, treatment and vaccination, which have been poor in migrant communities (10-17). Engagement of migrant populations with health services has been shown to be affected by a number of common factors, including accessibility and language services, but qualitative studies have also identified culture specific understanding of hepatitis B as an important determinant of engagement (18-34).

As only approximately 15-25% of people with chronic HBV infection develop liver cirrhosis or HCC, many of those diagnosed derive limited health benefit from their diagnosis and can experience harm through anxiety and time lost to consultations. In societies where the disease is stigmatised the harms can be significant and may outweigh the benefits for some individuals. Significant stigma has been described in West African migrants in USA (28-32), and indigenous Ghanaians (35), as well as a number of Asian migrant populations (27, 34).

Thus to ensure cost effectiveness of HBV screening and to avoid harm a clear understanding of cultural attitudes to hepatitis B in migrant populations is required. In this paper we report the findings of a qualitative study that examined knowledge and perceptions of hepatitis B in a migrant Somali population. We chose to study a single ethnic group in order to achieve greater depth of enquiry into culture specific determinants of understanding of hepatitis B, including exploration of the role of language in perpetuation of misconceptions. The aim was to provide information to
foster culturally appropriate implementation of HBV screening and contact tracing to maximise engagement and minimise harm. We chose to study a Somali migrant population as, compared to West African and Asian populations, studies exploring the East African cultural understanding of Hepatitis B have been limited (27-34). Also, significant Somali migrant populations are present in a number of nations were hepatitis B testing is recommended, including USA, Canada, Netherlands and UK.

Approximately 97,000 people born in Somalia are living in the UK with large populations in London, Liverpool and Bristol where this study was based (36, 37). The Bristol Somali population numbers around 7,000 with a HBV prevalence of 2.9% (38) and was chosen for this study as the city hosts a strong community health advocacy enterprise which was expected to optimise study engagement.
Methods

Data was collected using qualitative research methods between February and July 2014. Adults of Somali ethnicity living in Bristol UK, were recruited through informal community networks by Somali community health advocates. Purposive sampling taking account of gender, age, levels of education, duration living in the UK and employment status was used to select participants to capture variation in views and experiences.

Recruits reporting that they had not previously been diagnosed with HBV infection were invited to participate in one of four focus groups which were organised separately for women (focus groups 1 and 2) and men (focus groups 3 and 4) and each comprised 4 to 8 recruits. Focus groups 1 to 3 were held in Somali with the assistance of an interpreter, focus group 4 was held in English. The focus groups explored the participants understanding of hepatitis B, and used targeted screening and contact tracing scenarios to understand barriers and triggers to engagement.

Recruits reporting that they had been previously diagnosed with hepatitis B infection were invited to participate in one-to-one interviews which aimed to explore their experiences of hepatitis B infection. Topic guides, informed by the Health Belief Model (39) were used to facilitate the focus group discussions and semi-structured interviews so perceived susceptibility and severity of hepatitis B, barriers and benefits, and cues to action as they related to hepatitis B testing could be explored.

Focus groups and interviews lasted approximately 1 hour, and were conducted in community centres convenient for participants.

Focus groups and interviews were audio recorded, transcribed, anonymized, checked for accuracy and then imported into the software package NVivo10. Data collection and analysis were conducted in parallel and continued until data saturation in major themes was reached (40). Data-driven inductive thematic analysis (41), was used to scrutinise the data in order to identify and analyse patterns across the dataset using constant comparison techniques (42). Transcripts were examined on a line-by-line basis and an initial coding frame developed by AC. A subset of transcripts was
independently analysed by JH to contribute to the generation and refinement of codes and thematic categories to maximize rigor.

All participants received written and verbal information about the research and provided written informed consent. Ethical approval for the study was obtained from the NHS National Research Ethics Service Committee London - Camden & Islington 13/LO/11/80.
Results

A total of 49 adults were approached of whom 30 participated. The mean age of participants was 50 years (range 32 to 71), 17 were women, 28 spoke Somali as their first language and all were Muslim. Participants varied in relation to education, language ability and hepatitis B exposure (Table 1). The analysis identified key themes which are illustrated below with the use of anonymised transcript extracts (Tables 2 to 4). Additional relevant extracts are provided as supplementary material. In the extracts ‘. . .’ indicates that words from the original verbatim quote have been omitted (repetition, digressions or unclear speech). Participants are identified by a pseudonym (A to H), and a focus group (number 1 to 4) or an interview (letter ‘i’).

Awareness, understanding and stigma of hepatitis B

Most participants were not familiar with the English language term ‘hepatitis B’ (Table 2). This included some who spoke English and had a high level of formal education. A minority of participants, particularly those who knew someone diagnosed with hepatitis B in Europe, had an appreciation of its major characteristics but felt that the disease was not well understood in the Somali community (Table 2 and supplementary data).

The few participants who were familiar with the term ‘hepatitis B’ often explained it within their group using the English term ‘jaundice’ or the Somali terms ‘Joonis’, ‘Cagaarshow’ and ‘agaarhou’ meaning yellowing or greening of the skin and eyes. Some participants used the terms hepatitis B and jaundice interchangeably, while others became confused about the use of the two terms (Table 2 and supplementary data).

When asked about the cause of hepatitis B (which had already become co-identified with jaundice within the groups), a change in diet or excess fatty food was most commonly voiced (Table 2). Drinking unclean water was also suggested, and three English speaking participants mentioned a virus or bacteria (there is no word in Somali for virus, bacteria or germ). When asked about
transmission, the majority who responded said they didn’t know how HBV was transmitted or how
to prevent transmission, while a few suggested it was transmitted by poor sanitation, sexual routes,
blood transfusion or sharing food (Table 2).

The focus group participants were unanimous that hepatitis B was not stigmatised in Somali culture,
and none of the four participants interviewed (who had been diagnosed with Hepatitis B) indicated
that they had felt stigmatised by their diagnosis. One interview participant suggested that though
jaundice was not traditionally stigmatised in Somalia, he felt that as people began to understand
more about it stigma was beginning to emerge (Table 2).

Response to public health messages

To explore targeted screening of migrants, examples of posters and letters (in English and Somali)
recommending hepatitis B testing of people born in high prevalence countri
es were discussed.
Participants were asked to consider how UK Somali’s would respond to the health messages
provided. The general response was positive, with all groups indicating that Somali’s would have a
desire and duty to look after their health and that of their family (Table 3).

There was consensus that the majority of UK Somali’s would not engage with hepatitis B posters, but
that a letter directly sent to them would usually prompt them to seek further information and
testing, (Table 3 and supplementary data). Reasons given for not attending for testing included
misconceptions of the nature of hepatitis B. For example, the misconception that ‘jaundice’ (and by
association hepatitis B) was a relatively trivial disease without long term consequences was
consistent across all focus groups (supplementary data), and was cited as a deterrent to testing and
to engagement with the information provided.

Misconceptions regarding the transmission route and natural history of the disease were also cited
as deterrents, with participants saying that some people in their community would feel that they
couldn’t have ‘jaundice’ (and thus hepatitis B) if they had a good diet, or had no symptoms (Table 3).

Finally, a number of participants said they believed that an unrelated visit to the doctor, some general blood tests or other health screening would pick up hepatitis B, and that this would deter testing.

In both the male focus groups participants expressed the view that Somali people would be suspicious of a public health intervention targeting a single racial group, and would find this stigmatising. An intervention targeted more widely was acceptable (Table 3).

Response to contact tracing was explored through the scenario of a newly diagnosed Somali who is informed by his/her GP of the transmission routes, and advised that his/her partner, children and other family members living in the same house should be tested and vaccinated. There was consensus that the person with hepatitis B has a strong duty to disclose given that the disease is transmissible, and that telling their contacts that they had hepatitis B (or jaundice) would be easy as there is no stigma or embarrassment associated with the disease (Table 3). This expectation was backed up in the one-to-one interviews where all participants asked (three of the four) said they had disclosed to their family.

While it was considered easy to disclose the diagnosis, there was consensus that explaining the transmission routes and the risk of cirrhosis or cancer would be difficult, as these would not concur with expected attributes of ‘jaundice’ (Table 3). Again, this difficulty was confirmed by the interviewees.

An additional theme that emerged from the female focus groups was concern that male partners might not attend for testing and vaccination (supplementary data). Reasons given were that if the man was healthy, he wouldn’t feel he needed to go, or that he was likely to believe that his health had already been checked, or that men in general are reluctant to go to the doctor. The idea that men would not take the risk seriously was also expressed by one of the interview participants (Table 3).
In the male focus groups there was acknowledgement that women would be more concerned than
men, but the majority voice was that most male Somali contacts would attend for testing and
vaccination. When asked why some male contacts might not go, the only reason volunteered was
lack of understanding (supplementary data).

Overcoming barriers to engagement

When asked what would increase engagement with testing and contact tracing, ‘information’ was
suggested most frequently across all focus groups. Where the facilitator questioned whether
information alone would be sufficient to reverse misconceptions, it was felt that it would. For
example, regarding symptoms, there appeared to be no conceptual resistance to the possibility of an
asymptomatic disease, rather symptoms were expected for this particular disease (‘jaundice’).

The most effective media for delivery of information was discussed. To increase awareness of
hepatitis B, radio, television and group discussions were suggested as useful, with oral
communication generally regarded as more effective than written (Table 4). To attract people for
testing, the consensus was that letters addressed to individuals would have a big impact so long as
they were translated properly into Somali (Table 4), and that people could be supported to attend by
talking to a member of the Somali community who had experience of hepatitis B (supplementary
data). Other written information was also valued, particularly during the process of contact tracing
where a proposal to supply the index case with written information for the contact was welcomed
(supplementary data).

Regarding information content participants emphasised that sufficient information should be
presented so the person can understand the disease and overcome their misconceptions. The
information most commonly cited as important was that hepatitis B could result in a serious or fatal
outcome (Table 4). Participants were also concerned that information regarding targeted testing of
migrants should be explicit in the inclusion of migrants from a number of continents not just Africa in order to avoid generation of stigma against Africans.

Discussion

This study explored understanding of hepatitis B and response to targeted screening and contact tracing from the perspective of a UK migrant Somali population. To our knowledge this study is the first to address these issues in a Somali population. Strengths of the study include the diverse background and demographic of our participants, and the use of interpreters to explore the opinions of non-english speaking participants. Limitations include the restricted geographic area for recruitment.

We found no common cultural understanding of hepatitis B. Of interest, participants who initially had no understanding of hepatitis B, came to co-identify hepatitis B with jaundice both through explanations from other group members, and through translation of hepatitis B into words meaning jaundice by interpreters. This progression occurred in all the focus groups, and is likely to be reflected outside the research setting as translation of ‘hepatitis B’ into terms meaning jaundice is common in medical interpretation and in currently available patient information leaflets in print and on line (43, 44). As jaundice (and the Somali terms ‘joonis’, ‘cagaarshow’ and ‘agaarhou’), indicates having yellow skin or eyes, this co-identification is in direct conflict with the largely asymptomatic nature of hepatitis B. Given migrant screening and testing of contacts aims to diagnose the infection during its asymptomatic phase, co-identification with jaundice may be a barrier to testing.

A number of the other misconceptions we observed may be based on experience of other diseases causing jaundice. For example, hepatitis A, which is a common cause of jaundice in Somalia, is transmitted through unclean food and water, and is usually a relatively trivial disease from which recovery is complete. Lack of awareness and diverse understandings of hepatitis B, including some of the concepts reported here, have been described in previous studies of migrant populations (27,
45), but the key role of translation of ‘hepatitis B’ into words meaning ‘jaundice’ in generation of misconceptions has not previously been suggested.

The Health Belief Model (39) components of perceived susceptibility and severity, perceived benefits, barriers, and cues to action, have been used to explain why individuals’ decide, or not, to attend hepatitis B screening across diverse ethnic groups, (46) (47). We found that the Bristol Somali population voiced factors cognisant with perceived susceptibility and severity as major influences on decisions regarding testing. Thus the perceived non-susceptibility associated with lack of symptoms, a healthy lifestyle and previous health checks; and the perceived non-severity of ‘jaundice’ were all cited as deterrents to testing in our study. In terms of perceived benefit, the ability to protect their family through vaccination was voiced as highly valued. Structural and cultural barriers to testing were not prominent, with the overriding opinion being that if misperceptions regarding susceptibility and severity could be overcome, then testing would be sought.

Our findings suggest that public health initiatives to promote hepatitis B testing in Somali migrant populations should prioritise provision of clear information about the natural history of hepatitis B to address misperception of low susceptibility and low severity, and should be cognisant of the role of language in creation and perpetuation of misconceptions. Specifically, patient information provided for Somalis should avoid translation of the term ‘hepatitis B’ into terms meaning jaundice, should acknowledge but refute the erroneous co-identification of hepatitis B with jaundice, and should emphasise the following points: 1) hepatitis B is usually asymptomatic; 2) hepatitis B can affect you whatever your diet and lifestyle; 3) hepatitis B can cause severe illness; 4) standard health checks and blood tests will not pick up hepatitis B. Regarding the delivery of information, the preference indicated in our focus groups for oral and community based methods is in keeping with the strong oral tradition within Somali culture, and suggests that radio, TV, community discussion groups and opportunistic conversation with health professionals would be preferred methods.
Community health education has been successful in other public health initiatives in Somali communities in the UK (48).

Our observations highlight that clear written information may be beneficial for people newly diagnosed with hepatitis B, to help them explain to their contacts the rationale behind testing and vaccination. Studies of hepatitis B contact tracing generally show poor uptake (14-17), indicating room for significant public health benefit.

Unlike the qualitative research observations in West African populations where stigma towards hepatitis B was a barrier to screening, and a cause of non-disclosure (28, 31), our findings suggest that hepatitis B is not a stigmatised disease in the Somali community in Bristol, and stigma is not a factor influencing testing or disclosure. We found some concern that hepatitis B may become stigmatised as knowledge increases, and, as stigma has been negatively associated with testing in other migrant communities (25, 26, 45), care should be taken to avoid undue emphasis of potentially stigmatising aspects of the disease. Of more concern to our participants was that targeted testing of migrants could stigmatise the targeted communities. Recent prevalence data suggests that narrowing the target migrant population for screening by country of birth may be justified on cost effectiveness grounds (38) increasing the potential for stigmatisation.

In conclusion, this study suggests that migrant Somalis in a large UK city feel a duty to look after their health and that of their family, but have low awareness and understanding of hepatitis B, tend to discuss hepatitis B using terms meaning ‘jaundice’, and harbour a number of disease misconceptions. The lack of awareness and misconceptions represent likely barriers to engagement with targeted screening and contact tracing which could be addressed through provision of culturally appropriate information. The likely role of translation in generating misconceptions should prompt a wider assessment of the knock on effects of the specific terms used in medical interpretation.
Acknowledgements

We would like to thank Sahra Aden, Mohamed Elmi and Ejaz Ahmad, for their invaluable roles in participant recruitment, facilitation and interpretation; Lorna Sweeney for advice regarding focus group structure and Matt Hickman for assistance with project initiation. This study has been supported with an educational grant via the Gilead UK and Ireland Fellowship Programme. The funder had no role in the design, execution or analysis of the study, the writing of the manuscript or the decision to submit for publication.

Conflict of interest

The authors report that apart from the study funding (documented in the acknowledgements), both AC, PC and JH have no conflicts of interest to declare.

Key points

• This study suggests that lack of awareness and misconceptions of hepatitis B are major barriers to testing in migrant Somalian populations.

• Perceived non-susceptibility and non-severity emerge as important disincentives to testing.

• Public health initiatives to raise awareness and knowledge should be careful to avoid increasing misconceptions and introducing stigma.

• Particular attention should be paid to language in order to avoid co-identification of hepatitis B with jaundice.

• The current lack of stigma and strong cultural duty of care for the family facilitates contact tracing in this population.

| Overcoming barriers to testing and contact tracing | Facilitator: “So do you think it would be possible to have a condition that was damaging your liver and you would still feel completely well?”
Mrs E2: “Yes, because sometimes you have a serious problem and you don’t know.”
Facilitator: “Would there be anything that would help her to go? That makes it easy for her to go?” [referring to woman receiving advice to attend for a hepatitis B test]
Mrs C1 or A1: “What can make her go maybe her family, if they’re worried about, they may encourage her or maybe somebody who has an experience about hepatitis B, You know, maybe friends? Somebody who knows about this or had hepatitis themselves may encourage her.”
Facilitator: “And is there anything else you think we should put in the letter or something we should take out of the letter to make it more likely to get Amina [fictional character from scenario] to go to her GP?”
Mrs D1: “If she understands what hepatitis B is, then she will definitely go, so the letter must be clear.”
Mrs A1: “The language that you write the letter in might make a difference, for example she might not be able to read English but she might be able to read Somali.”
Facilitator: “So what exactly should the letter say?”

Mr F3: “I think it would be emphasised more what is just mentioned here, er, ... more about the process, saying that this hepatitis B worsening to be a killer or fatal at the end, so people telling him how it develops even if you feel well, how it comes to an irreversible state or fatal, so if a lot of thought or literature is given to that then I think people will understand.”
