HORIZONTAL STIFFNESS & DAMPING OF PILES IN INHOMOGENEOUS SOIL

Xenia KARATZIA¹ and George MYLONAKIS²

Abstract: A practically-oriented analytical procedure for determining the dynamic stiffness and damping (impedance coefficients) of a laterally-loaded pile in soil exhibiting different types of inhomogeneity with depth, is presented. To this end, an energy method based on the Winkler model of soil reaction in conjunction with pertinent shape functions for the deflected shape of the pile, are employed. A new elastodynamic model for the wave field around a pile is also introduced. The method is self-standing and free of empirical formulae or constants. Dimensionless closed-form solutions are derived for: (1) the distributed (Winkler) springs and dashpots along the pile; (2) the dynamic stiffness and damping coefficients at the pile head; (3) the “active” length beyond which the pile can be treated as infinitely long; (4) the relative contributions to the overall head stiffness and damping of the soil and the pile media. Swaying, rocking and cross swaying-rocking impedances are considered for parabolic, exponential, and multi-layered inhomogeneous soil. The predictions of the model compare favorably with established solutions, while new results are presented. An illustrative example is provided.

Keywords: pile, stiffness, damping, closed-form solution, soil-structure interaction, radiation damping.

INTRODUCTION

Systematic research over the past decades on the dynamics of laterally-loaded piles has resulted in a wide set of analysis methods that can be used in design. These methods can be classified in two broad groups: 1) those based on the beam-on-Winkler-foundation model, and 2) those based on the continuum model. Reviews of the subject have been presented, among others, by Pender (1993) and Gazetas & Mylonakis (1998).

With reference to the first group of methods, the assumption of an Euler-Bernoulli beam for the pile is usually valid, since most piles are sufficiently slender so that shear deformations in their body can be neglected. On the other hand, the representation of the restraining action of soil via independent springs distributed along the pile axis is not straightforward, since the spring modulus cannot be determined by elementary means ignoring soil-structure interaction such as borehole data (Mylonakis 2001; Basu & Salgado 2008; Guo 2012). Moreover, the common assumption of uniform soil stiffness is usually unrealistic, as overburden stresses combined with over-consolidation and stress-induced nonlinearities due to pile installation and subsequent loading typically result in soil stiffness varying with depth. Due to inherent difficulties in handling variable material properties analytically, there is a lack of solutions for the response of piles in inhomogeneous soil (Syngros 2004; Basu & Salgado 2008; Guo 2012). Indeed, exact analytical solutions obtained by means of Winkler models are restricted to the idealized case where soil modulus increases proportionally with depth i.e., a triangular distribution, and static conditions (Hetenyi 1946). These solutions are expressed in terms of infinite power series, which are hard to implement in practice. Analytical solutions for dynamic loads based on more rigorous methods are not available.

A variant of the subgrade reaction method is the p-y method, which is widely employed in the offshore industry for large amplitude static or low-frequency loads (Guo 2012). Extending the method to dynamic conditions is not straightforward given the theoretical difficulties in
handling non-linear dynamic effects and the scarcity of experimental data (Gerber & Rollins, 2008). Another drawback of this approach is the site-specific nature experimentally obtained $p$-$y$ curves which do not fully respect the three-dimensional aspects of pile-soil interaction (Basu & Salgado, 2008).

With reference to the second group of methods, numerical solutions to the problem have been published, among others, by Banerjee & Davies (1978), Kulhemeyer (1979), Poulos & Davis (1980), Randolph (1981), Kaynia & Kausel (1982), Budhu & Davis (1987) and El-Marsafawi et al (1992) using a variety of analytical techniques including finite-difference, finite-element, boundary-element and various hybrid formulations in three dimensions. These methods are mathematically involved and, thereby, not appealing to geotechnical engineers.

With the exception of a few fitted formulas pertaining to linearly- and parabolically-varying stiffness with depth (Randolph 1981; Budhu & Davis 1987; Gazetas 1991; Syngros 2004), little information is available about pile stiffness and damping in inhomogeneous soil media. The aim of this paper is to develop a theoretically sound, yet practically-oriented analysis procedure for determining the dynamic stiffness and damping of flexible laterally-loaded piles considering more general types of soil inhomogeneity. To this end, the following novel solutions are presented and discussed:

1. a 2D elastodynamic model for the modulus of the distributed dashpots along the pile,
2. a 3D elasticity solution for the modulus of the distributed springs,
3. an energy method for the stiffness and damping coefficients at the pile head.

The method allows for closed-form solutions to be obtained for a variety of soil profiles, including a multi-layer one which can handle any type of vertical inhomogeneity. Unlike existing approximate methods employing fitted formulas to finite-element solutions, the procedure is self-standing and does not involve empirical information. Moreover, the method
can be extended to model, in an iterative manner, nonlinear problems via pertinent p-y relations – although such applications are not examined here (Gerolymos & Gazetas, 2005b).

The problem investigated is depicted in Fig. 1a: a laterally-loaded pile embedded in a soil profile whose stiffness varies with depth, loaded by a concentrated force and/or a moment at the head. The pile is considered a linearly visco-elastic solid cylindrical beam of diameter $d$, Young’s modulus $E_p$ and linear hysteretic damping $\beta_p$. It is also assumed that the pile is sufficiently long so that it deforms only up to a certain depth, $L_a$ – known in the literature as “active length”, which is typically on the order of ten pile diameters (Kulhemeyer 1979; Randolph 1981). The soil is modeled as a linearly viscoelastic medium of Young’s modulus $E_s$, Poisson’s ratio $\nu$, mass density $\rho_s$, and linear hysteretic damping $\beta_s$.

**SOIL DESCRIPTION**

Fig. 2 depicts three basic forms of soil stiffness variation with depth considered in this work:

a) a “generalized parabolic” profile in which soil Young’s modulus increases with depth according to a power law, starting from a finite value at the surface; b) a profile in which soil stiffness varies exponentially between two finite values at zero and infinite depth, respectively – to be referred in the ensuing to as an “exponential” profile, and c) a multi-layer profile with each horizontal layer having arbitrary thickness and material properties.

Of these soil conditions, the third and certain special cases of the first (e.g. the case where stiffness increases proportionally with depth) are the ones adopted in most of the literature. The second profile has been first treated, for a different class of geotechnical problems, by Selvadurai et al. (1986) and Vrettos (1991).

The generalized parabolic variation of soil Young’s modulus with depth depicted in Fig. 2a is described by the equation

$$E_s(z) = E_{sd} \left[ a + (1-a) \frac{z}{d} \right]^n$$

(1)
where $E_{sd}$ denotes soil Young’s modulus at depth of one pile diameter ($z=d$), while $a$ and $n$ are dimensionless inhomogeneity parameters.

Setting $z = 0$ in Eq. (1), $a$ is obtained as

$$a = \left( \frac{E_{so}}{E_{sd}} \right)^{\frac{1}{n}} \quad (2)$$

where $E_{so}$ stands for the soil Young’s modulus at the surface. The exponent $n$ typically varies between zero and one, corresponding to over-consolidated and normally consolidated clay, respectively. A value of one half pertains to uncemented granular soil such as sand (Darendeli 2001; Muir Wood 2004).

With reference to the modulus of the Winkler springs, it is postulated that $k(z)$ follows the same variation with depth as $E_s(z)$ i.e.,

$$k(z) = k_d \left[ a + \left(1 - a \right) \frac{z}{d} \right]^n \quad (3)$$

where $k_d$ denotes the value of the spring constant at the depth of one pile diameter.

Both $k_d$ and $E_{sd}$ are measured in units of pressure and are related through

$$k_d = \delta E_{sd} \quad (4)$$

$\delta$ being a dimensionless coefficient typically varying between 1 to 2 depending on variation of soil stiffness with depth, pile-soil stiffness contrast and boundary conditions at the pile head (Novak et al 1978; Roesset 1980; Scott 1981; Dobry et al 1982; Gazetas & Dobry 1984; Syngros 2004; Karatzia et al 2014).

With reference to radiation damping, it is known from dimensional considerations (Kuhlemeyer 1979) that the dashpot coefficient $c_r$ is proportional to soil shear wave velocity $V_s$ (i.e., $\sqrt{E_s}$). Accordingly, as a first approximation, one may write

$$c_r(z) = c_{rd} \left[ a + \left(1 - a \right) \frac{z}{d} \right]^{n/2} \quad (5)$$
which reveals a weaker dependence of $c_r$ on depth compared to $k$ in Eq. (3). In the above equation $c_{rd}$ stands for the dashpot modulus at $z = d$. Frequency effects on radiation damping are discussed later in this article.

Bounded soil inhomogeneity with depth, depicted in Fig. 2b, can be taken into account by considering an exponential variation in Young’s modulus with depth of the form (Vrettos 1991)

$$E_s(z) = E_{s0} \left[ b + (1-b)(1-e^{-qz/d}) \right]$$  

(6)

in which $b$ stands for the ratio of Young’s moduli at the surface ($E_{s0}$) and at infinite depth ($E_{so}$), while $q$ is a dimensionless inhomogeneity parameter controlling the rate of increase or decrease in stiffness.

In the same vein as in Eqs (3) and (5), the moduli of the Winkler springs and dashpots for the case of bounded soil inhomogeneity can be written as

$$k(z) = k_{d} \cdot \frac{b + (1-b)(1-e^{-qz/d})}{b + (1-b)(1-e^{-qz/d})}$$  

$$c_r(z) = c_{rd} \cdot \left( \frac{b + (1-b)(1-e^{-qz/d})}{b + (1-b)(1-e^{-qz/d})} \right)^{1/2}$$  

(7a,b)

with $k_d$ and $c_{rd}$ having the same meaning as before.

Bounded inhomogeneity such as that expressed by Eqs (6) and (7) might be preferable over the unbounded one in Eqs (1) to (5) for deep soil profiles. However, for shallower profiles either form may be suitable and the selection should be made on a case by case basis.

**RADIATION DAMPING MODEL**

Several simplified models based on different assumptions regarding wave propagation in the soil have been proposed for evaluating the distributed radiation dashpot coefficient along the pile. Fig. 3 illustrates a number of radiation damping schemes. A brief reference to these mechanisms is useful and reveals salient features of the proposed analysis.
The stripe model of Berger et al (1977) assumes 1D wave propagation in an infinitely long constrained rod and a viscous dashpot which fully absorbs the energy of the emitting waves. Despite its simplicity, this model lacks realism because it provides a strictly frequency-independent $c_r$ with high sensitivity to Poisson’s ratio, producing an infinite amount of damping as $\nu$ approaches 0.5. A more rigorous approach has been followed by Novak et al (1978), who proposed a 2D plane-strain model. In this idealization, the soil is divided into an infinite number of thin horizontal “slices”, with each slice subjected to dynamic plane-strain deformation (i.e., $\varepsilon_z = 0$). The resulting radiation damping coefficient is frequency-dependent and decreases monotonically with frequency. The validity of this model has been demonstrated in the works of Blaney et al (1976) and Roesset (1980).

An alternative plane-strain scheme has been developed by Gazetas & Dobry (1984). The basic assumption is that the circular cross section of the foundation can be approximated by a square cross section and the surrounding soil is divided into four trapezoidal zones. This formulation allows each of the zones to be analyzed separately as a two-dimensional truncated cone, with compression and extension taking place along the direction of the imposed load and pure shear developing in the perpendicular direction. Based on this formulation, the authors derived an approximate, frequency dependent radiation damping coefficient $c_r/(d\rho_s V_s) = \{(1/(2\pi))^{1/4}[1+(V_s/V_c)^{-5/4}]a_0^{-3/4}, with a_0 ((= \omega d/V_s) being the familiar dimensionless frequency, $\omega$ being the cyclic excitation frequency and $V_c$ standing for the compressional wave propagation velocity in the soil, which was empirically set equal to the so-called Lysmer’s analog wave velocity $V_{La} (= 3.4V_s/\sqrt{\pi(1-\nu)})$.

An alternative plane-strain model, henceforward referred to as an “infinitesimal sector model”, is illustrated in Fig. 3d. Contrary to the earlier formulation, in the present model the soil is divided into an infinite number of thin independent sectors, with each sector responding to dynamic compression and shearing independent of the others. Under this
physically-motivated assumption the circular cross section does not need to be replaced by a rectangular one. It is further assumed that each of the independent infinitesimal sectors emits shear and compressional waves, considering that in the loading direction and the perpendicular one propagate only compressional and shear waves, respectively. Shear waves are assumed to propagate with velocity $V_s$, while compression waves propagate with velocity $V_c$. As shown in the Supplemental Data File, each sector possesses an infinitesimal amount of stiffness expressed in the global reference system as a function of the polar angle $\phi$ defined in Fig. 3d and the dimensionless frequency $a_0$.

By integrating the contributions of all sectors, it is easy to show that the spring and the radiation damping coefficient in an undamped soil medium are, respectively

$$\frac{k}{G_s} = \pi a_0 \frac{1}{2} \text{Re}[\Lambda] \quad , \quad \frac{c_r}{d\rho_s V_s} = \frac{1}{2} \text{Im}[\Lambda] \quad (8a,b)$$

where,

$$\Lambda = \left(\frac{V_s}{V_c}\right)^{-1} \frac{H_i^{(2)} \left(\frac{1}{2} a_0 \right) V_s}{H_i^{(2)} \left(\frac{1}{2} a_0 \right) V_s} + \frac{H_i^{(2)} \left(\frac{1}{2} a_0 \right) V_c}{H_i^{(2)} \left(\frac{1}{2} a_0 \right) V_c} \quad (9)$$

is a dimensionless function of frequency, $H_0^{(2)}$ and $H_1^{(2)}$ being, respectively, the zero- and first-order Hankel functions of the second kind.

The relationship in Eqs (8b) and (9) is identical to that of Gazetas & Dobry (1984), except for the generic velocity ratio ($V_s/V_c$) – instead of an empirically defined compression velocity of the earlier model – and the absence of a multiplier $\pi/4$, which reflects the ratio of the side length to the diameter of a square pile cross section and a circular one, respectively, of equal perimeters. Evidently, these differences do not affect the functional form of the solution, yet may have an appreciable impact on the numerical results, as demonstrated in the following.

It should be noticed that contrary to the aforementioned models, the horizontal soil slices are considered here to be semi-restricted (i.e., it is assumed that the vertical dynamic stress...
increment $\sigma_z$ is zero, instead of the corresponding shear strain $\varepsilon_z$, a superior approximation accounting for the effect of the free surface and leading to solutions not strongly dependent on Poisson’s ratio, in agreement with rigorous numerical solutions of related problems (Veletsos & Younan 1995; Anoyatis & Mylonakis 2012). In light of this assumption, $V_s/V_c = (1-v)/2$. A detailed discussion of this equation is provided in Anoyatis et al (2016).

A comparison of the predictions of the proposed model against those available in the literature is provided in Fig. 4a for the cases where $v = 0.25$ and 0.4. Evidently, there is good agreement between the four solutions. The Tabesh & Poulos (2000) proposal of $c_r = 5dp_sV_s$ seems to provide a reasonable approximation for dimensionless frequencies $a_0$ on the order of 1. At higher frequencies it can be shown that $\Lambda$ approaches asymptotically the purely imaginary value $i[1+(V_s/V_c)^{-1}]$ and, thereby, the radiation dashpot $c_r$ becomes frequency independent while the spring constant vanishes, as in the one dimensional case.

Using non-linear regression analysis by means of the Levenberg-Marquardt method (Bevington and Robinson 1992) in the results of Fig. 4b in the frequency range $0.1 < a_0 < 1$, the following predictive equation is derived

$$\frac{c_r}{d\pi \rho V_s} = \left[0.25 + 0.8 \left(\frac{V_s}{V_c}\right)^{-1}\right] a_0^{0.4}$$

which can be used in applications. It must be noted that the infinitesimal sector model also provides information on Winkler spring stiffness (Eq. 8a). However, the stiffness tends to zero both at low and high frequencies and, thereby, the solution is of limited value. An enhanced stiffness model is presented later in this article.

PILE STIFFNESS MODEL

Under harmonic oscillations, the equation of motion of a uniform pile attached to a Winkler foundation with variable modulus $k(z)$ and $c_r(z)$, is (Mylonakis 1995)
\[ E_p I_p \frac{d^2 Y}{dz^2} + \left[ k(z) - m \omega^2 + i \omega c_r(z) \right] Y = 0 \] (11)

where \( Y = Y(z) \exp[i \omega t] \) is the harmonic pile deflection as a function of depth \( z \); \( E_p I_p \) is the pile flexural stiffness, \( m \) is the pile mass per unit length, \( k(z) \) and \( c_r(z) \) are the moduli of Winkler springs and dashpots, \( \omega \) being the cyclic excitation frequency and \( i = \sqrt{-1} \).

In case of a homogeneous soil layer, solving Eq. (11) is straightforward. The associated impedance coefficients in swaying, rocking and cross swaying-rocking are, respectively (Scott 1981; Dobry et al 1982; Pender 1993; Mylonakis 1995)

\[ K_{hh} = 4E_p I_p \lambda^3, \quad K_{rr} = 2E_p I_p \lambda, \quad K_{hr} = 2E_p I_p \lambda^2 \] (12a-c)

where

\[ \lambda = \left[ \frac{k + i \omega c_r - m \omega^2}{4E_p I_p} \right]^{1/4} \] (13)

is a Winkler parameter, measured in units of 1/Length, which can be interpreted as a wavenumber controlling the attenuation of pile deflection with depth.

The basis of the proposed solution is that the unknown deflection function \( Y(z) \) in Eq. (11) can be effectively represented by a pair of approximate, twice differentiable, dimensionless unitary functions \( \chi(z) \) and \( \varphi(z) \) (Fig. 1). Of these functions, \( \chi(z) \) represents the normalized deflected shape of the pile due to a unit head displacement under zero rotation (Fig. 1b), whereas \( \varphi(z) \) is the corresponding deflected shape due to a unit head rotation under zero displacement (Fig. 1c). For long piles, \( \chi(z) \) and \( \varphi(z) \) can be well approximated by the deflected shape of a long pile in homogeneous soil (Karatzia & Mylonakis 2012):

\[ \chi(z) = e^{-\mu z} \left[ \sin(\mu z) + \cos(\mu z) \right], \quad \varphi(z) = \frac{e^{-\mu z}}{\mu} \sin(\mu z) \] (14a,b)

For a free-head pile loaded by a horizontal head force, the corresponding function is (Fig. 1d)

\[ \psi(z) = e^{-\mu z} \cos(\mu z) \] (14c)
In the above equations $\mu$ is a shape parameter analogous to the wavenumber $\lambda$ in Eq. (13). In homogeneous soil $\lambda$ and $\mu$ coincide. In non-homogeneous soil $\mu$ can be taken as the mean value of $\lambda$ within the active length, $L_a$, of the pile i.e.,

$$\mu = \frac{1}{L_a} \int_0^{L_a} \lambda(z, \omega) \, dz$$

(15)

It should be noticed that $L_a$ is defined as the length beyond which the pile behaves as a semi-infinite beam that is, an increase in pile length would lead to an asymptotic change (increase or decrease) in lateral stiffness at the pile head, regardless of boundary conditions at the tip. Pertinent expressions for $L_a$ in various soil profiles are derived in the following.

Replacing $Y(z)$ in Eq. (11) with $Y_o \chi_i(z)$, $Y_o$ being the amplitude of motion at the pile head, multiplying by $Y_o \chi_j(z)$, $X_i, X_j$ being any of the shape functions in Eqs (14a) and (14b), and integrating over the length of the pile, it can be easily shown (Mylonakis & Roumbas 2001; Karatzia & Mylonakis 2012) that the stiffness and damping coefficients atop the pile can be determined from the virtual-work equations

$$K_{ij} = E_p I_p \int_0^L X_i''(z) X_j''(z) \, dz + \int_0^L k(z) X_i(z) X_j(z) \, dz - m \omega^2 \int_0^L X_i(z) X_j(z) \, dz$$

(16a)

$$C_{ij} = \frac{2 \beta_p E_p I_p}{\omega} \int_0^L X_i''(z) X_j''(z) \, dz + \frac{2 \beta_t}{\omega} \int_0^L k(z) X_i(z) X_j(z) \, dz + \int_0^L c(z) X_i(z) X_j(z) \, dz$$

(16b)

which are analogous to energy approximations used in finite-element procedures (Clough & Penzien 1975; Mylonakis 1995). Note that the first two terms in the right-hand side of Eq. (16a) stand for the contribution to the overall stiffness of pile flexural stiffness and soil stiffness, respectively. The contribution of pile inertia to stiffness (third term in Eq. 16a) is typically minor and, thereby, is omitted in the remainder of this work. Accordingly, pile head stiffness can be well approximated by its static value in the frequency range of interest in earthquake engineering applications (Kaynia & Kausel 1982).

In Eq. (16b), the first two terms stand for the contributions to overall damping of the pile and the soil material damping, respectively, while the last term corresponds to the contribution of
soil radiation damping. The method was first employed in the analysis of pile foundations by Dobry et al. (1982) and later by Gazetas & Dobry (1984), who determined the swaying damping coefficient $C_{hh}$ using Eq. (16b) in conjunction with a numerically-evaluated shape function for a fixed-head pile. The subscripts $i$ and $j$ in the above formulation refer to different vibrational modes (i.e., swaying and rocking). For instance, using $\chi_i(z) = \chi_j(z) = \chi(z)$ the swaying impedance coefficients $K_{hh}$ and $C_{hh}$ are obtained. Similarly, setting $\chi_i(z) = \chi_j(z) = \phi(z)$, Eqs (16a,b) yield the rocking impedance coefficients $K_{rr}$ and $C_{rr}$. Finally, using $\chi_i(z) = \chi(z)$ and $\chi_j(z) = \phi(z)$ generates the cross swaying-rocking impedances $K_{hr}$ and $C_{hr}$. It is implicitly assumed that $\chi(z)$ and $\phi(z)$ are real-valued, obtained by static considerations. Also, for $L > L_a$ the analysis can be simplified by considering the pile as infinitely long, thereby increasing the upper integration limit in Eqs. (16a,b) to infinity. These approximations have been established in earlier studies by Dobry et al. (1982), Mylonakis (1995) and Mylonakis & Gazetas (1999).

To develop insight into the physics of the solution, it is useful to adopt a representation of pile head stiffness in the form

$$K_y = K_y^p (1 + S_y)$$

(17)

where $K_y^p$ denotes the contribution to the overall head stiffness of pile flexural stiffness (first integral in Eq. 16a) and $S_y$ is a dimensionless coefficient which stands for the contribution of the restraining action of soil (second integral in Eq. 16a normalized by the first). Accordingly,

$$K_{hh} = E_p I_p \mu^2 (1 + S_{hh}) \quad , \quad K_{rr} = \frac{3}{2} E_p I_p \mu (1 + S_{rr}) \quad , \quad K_{hr} = E_p I_p \mu^2 (1 + S_{hr})$$

(18a-c)

which correspond to the swaying, rocking and cross-swaying-rocking mode, respectively. For homogeneous soil the coefficients $S_{ij}$ equal 3, 1/3 and 1, respectively, according to Eq. (12). In addition, using the normalized damping coefficient at the pile head
\[ \beta_y = \frac{\omega C_y}{2K_y} \]  

(19)

Eq. (16b) yields the dimensionless expression

\[ \beta_y = w_{ij}^p \beta_p + (1 - w_{ij}^p) \beta_s + w_{ij}^r \beta_{rd} \]  

(20)

where \( w_{ij}^p, w_{ij}^r \) are dimensionless coefficients which stand for the contribution to the overall damping of pile material damping and radiation damping, respectively. These coefficients are dependent on the response mode, type of soil inhomogeneity and \( E_p/E_{sd} \) ratio.

The distributed radiation damping coefficient along the pile, \( \beta_{rd} \), is

\[ \beta_{rd} = \frac{\omega C_{rd}}{2k_d} \]  

(21)

c_{rd} being the value of the radiation dashpot at \( z = d \).

In the realm of the proposed elastodynamic model, \( \beta_{rd} = \pi \text{Im}[A] a_{0d} / [8(1+v) \delta] \) (following Eqs. 4, 8b), \( a_{0d} \) being the dimensionless frequency at depth \( z = d \) (i.e., \( \omega d / V_{sd} \)).

By matching Eqs. (20) and (16b), the weight factors \( w_{ij}^p \) are related to \( S_{ij} \) in Eq. (17) through

\[ w_{ij}^p = \frac{1}{1 + S_{ij}} \]  

(22)

which suggests that the dimensionless coefficients \( S_{ij} \) and \( w_{ij}^r \) (six factors in total) suffice to describe the dynamic impedance of a cylindrical pile in planar oscillations.

**WINKLER SPRING STIFFNESS MODEL**

Key to the implementation of the proposed method is the appropriate selection of the Winkler spring coefficient \( \delta \) in Eq. (4). This can be done based on a three-dimensional elasticity model for the response of a horizontal soil slice proposed by the senior author (Mylonakis 2001). The difference with the slice model in Fig. 3d lies in the horizontal inter-slice shear tractions at the upper and lower faces of the slice which are accounted for, providing finite
stiffness at all frequencies. The above solution (which contains some clerical errors in the
original publication), is further explained in Karatzia et al (2014, 2015) and can be cast as

\[
\delta = \frac{2\pi \eta^2}{(1+v)} \left[ \ln \left( \frac{\eta_u (4/\alpha_c)^{1/\eta_u}}{1+\eta_u} \right) - \gamma (1+\eta_u)^{-1} \right] \quad (23)
\]

where \( \eta_u = [(2-v)/(1-v)]^{1/2} \) is a compressibility coefficient, \( \gamma = 0.577 \) is Euler’s number, and \( \alpha_c \) is a dimensionless parameter accounting for the variation of pile displacement with depth

\[
\alpha_c = d \left( \int_0^a G_s(z) Y'(z)^2 \, dz / \int_0^a G_s(z) Y(z)^2 \, dz \right)^{1/2} \quad (24)
\]

where \( Y = Y(z) \) is the deflected shape of the pile in Eq. (11) (Eqs 14a-c for various response
modes) and \( G_s(z) = E_s(z) / 2(1+v) \) is the depth-varying soil shear modulus.

Evaluating Eq. (24) yields

\[
\alpha_c = \chi_s \left( E_p / E_s \right)^{n_\delta} \quad (25)
\]

with \( \chi_s \) and \( n_\delta \) given in Table 1 for different soil profiles and pile head constraints. It is worth
noting that in a shallow soil layer over a rigid base, parameter \( \alpha_c \) can be interpreted as a
cutoff frequency beyond which propagating waves suddenly emerge in the soil. However, for
the more general conditions at hand, \( \alpha_c \) can be viewed as a stiffness parameter.

A comparison of the predictions of Eq. (23) against available formulas for parameter \( \delta \) is
performed graphically in Fig. 5, with reference to fixed- and free-head piles in homogeneous
soil. Evidently, the effect of pile head restraint is significant and becomes more pronounced
at low pile-soil stiffness contrasts. The proposed model captures satisfactorily this effect. In
general, parameter \( \delta \) is on the order of 1 and 2 for both fixed- and free-head piles, and tends
to decrease with increasing \( E_p/E_s \). The proposed analytical solution is in good agreement with
the available formulae, especially for stiff piles having \( E_p/E_s \) ratios greater than \( 10^3 \) or so.

Fig. 6 presents results for parameter \( \delta \) in different soil profiles obtained with the proposed
model. Clearly, \( \delta \) is sensitive to the type of soil profile attaining greater values in soil whose
stiffness varies with depth. This is hardly surprising as the gradient of Young’s modulus with
depth increases the interaction (“arching”) among soil slices at different elevations. With reference to the fixity condition at the pile head, parameter $\delta$ is much higher for free-head piles in the whole range of $E_p/E_{sd}$ values. A comparison of the present solution against results from the finite-element-based solution of Syngros (2004) is presented in the same graph. The accord between the proposed method and the numerical solution cannot be overstated especially for piles with $E_p/E_{sd}$ ratios greater than $10^3$ or so.

**ACTIVE PILE LENGTH**

It is well-known that the response of a laterally-loaded pile becomes essentially independent of pile length after a critical limit known as “active length”, $L_a$. Several empirical formulae have been proposed to estimate this parameter (Kuhlmeyer 1979; Poulos & Davis, 1980; Randolph 1981; Fleming et al 1993; Gazetas 1991; Budhu & Davies 1987; Mylonakis 1995; Syngros 2004; Guo 2012; Di Laora & Rovithis 2015). These are typically written in the form

$$L_a/d = \chi_L(E_p/E_{sd})^{n_L}$$

(26)

$\chi_L$ and $n_L$ being dimensionless constants; $n_L$ is of the order of 0.25 while $\chi_L$ lies in the range 1.5 to 2.5 depending mainly on type of soil profile and fixity conditions at pile head.

In the realm of the present model, a rational estimation of active pile length is possible by means of simple calculations. The investigation at hand focuses on both homogeneous and inhomogeneous soil. Based on Eq. (16a) and the developments of the previous sections, the following dimensionless equation is derived for the stiffness coefficient $K_{hh}$

$$\varepsilon_{tol} = \frac{E_p I_p \int_0^\infty \chi''(z)^2 \, dz + \int_0^\infty k(z) \chi(z)^2 \, dz}{E_p I_p \mu^3 + \int_0^\infty k(z) \chi(z)^2 \, dz}$$

(27)

in which $\chi(z)$ is the shape function in Eq. (14a) and $\varepsilon_{tol}$ stands for a tolerance parameter. In the above ratio, the denominator represents the stiffness coefficient $K_{hh}$ of an infinitely long pile whereas the numerator stands for the contribution of the portion of the pile below the active
length. Accordingly, a value of $e_{tol}$ equal to $10^{-2}$ suggests that 99% of the swaying stiffness $K_{hh}$ is contributed by the portion of the pile above $L_a$. Based on existing literature (Randolph 1981; Syngros 2004), $e_{tol}$ is usually taken in the range $10^{-2}$ to $10^{-3}$. Note that the formulation in Eq. (27) is general and can be applied to both homogeneous and inhomogeneous soil, as well as to different response modes.

By applying Eq. (27) to the soil profiles in Fig. 2 and using non-linear regression analysis of the Levenberg-Marquardt type over the range $10^2 < E_p/E_{sd} < 10^3$, the following relationship for the dimensionless parameters of the active pile length was obtained

$$\chi_L = \chi_1 - \chi_2 \log e_{tol}$$

(28)

parameters $\chi_1$, $\chi_2$ and $n_L$ are given in Table 2. The analysis reveals that the differences in the value of parameter $\chi_L$ in the literature could be attributed to the different tolerance limits adopted in different studies (Fig. 7).

It is worth mentioning that using the stiffness terms $K_{rr}$ or $K_{hr}$ instead of $K_{hh}$ in Eq. (27), one obtains approximately the same results for $L_a/d$ (not shown), which suggests that the effect of the response mode on active pile length is of minor importance.

Results for active pile length in various soil profiles obtained by means of Eq. (26) and Table 2 are illustrated in Fig. 7, plotted as a function of pile-soil stiffness contrast and different values of the tolerance parameter $e_{tol}$. In the same plot, available solutions from the literature are shown for comparison. Evidently, $L_a/d$ tends to increase with increasing $E_p/E_{sd}$ and decrease with increasing $e_{tol}$. The sensitivity of $L_a$ in $e_{tol}$ leads to a difference of three to four diameters for $E_p/E_{sd} = 10^3$. The proposed solution is in meaningful agreement with those in the literature. An alternative interpretation of active pile length based on the value of dimensionless product ($\mu L$) is provided in Di Laora and Rovithis (2015).
Multi-layer profile

For a soil profile consisting of \( N \) homogeneous layers up to the active length, the integrals in
Eqs. (16a,b) can be evaluated analytically. Expressed in terms of the dimensionless
parameters \( S_{ij} \) (Eqs. 17, 18), the stiffness coefficients at the pile head are obtained as follows:

\[
S_{hh} = \sum_{i=1}^{N} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ -e^{-2\mu z_i} \left[ 2 + \cos(2\mu z) + \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(29a)

\[
S_{rr} = \sum_{i=1}^{N} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ e^{-2\mu z_i} \frac{1}{3} \left[ -2 + \cos(2\mu z) - \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(29b)

\[
S_{hr} = \sum_{i=1}^{N} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ -e^{-2\mu z_i} \left[ 1 + \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(29c)

The dimensionless coefficients associated with the radiation damping (\( \beta_{ij} = \omega C_{ij} / (2K_{ij}) \))
are given below

\[
w_{hh}^r = \frac{1}{1 + S_{hh}} \sum_{i=1}^{N} \frac{\beta_{ri}}{\beta_{rd}} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ -e^{-2\mu z_i} \left[ 2 + \cos(2\mu z) + \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(30a)

\[
w_{rr}^r = \frac{1}{1 + S_{rr}} \sum_{i=1}^{N} \frac{\beta_{ri}}{\beta_{rd}} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ e^{-2\mu z_i} \frac{1}{3} \left[ -2 + \cos(2\mu z) - \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(30b)

\[
w_{hr}^r = \frac{1}{1 + S_{hr}} \sum_{i=1}^{N} \frac{\beta_{ri}}{\beta_{rd}} \left( \frac{\lambda_i}{\mu} \right)^4 \left\{ -e^{-2\mu z_i} \left[ 1 + \sin(2\mu z) \right] \right\}^{z_{b,i}}_{z_{t,i}}
\]

(30c)

with

\[
\mu = \frac{1}{L_i} \sum_{i=1}^{N} \int_{z_{h,i}}^{z_{t,i}} \lambda_i(z) \, dz
\]

(31)

in which \( z_{t,i} \) denotes the elevation of the upper end of layer \( i \), and \( z_{h,i} \) denotes the elevation of
the lower end (Fig. 2c); \( h_i \) is the thickness of the layer, \( \lambda_i \) is the corresponding pile
wavenumber and \( \beta_{ri} (= \omega c_{ri} / (2k_i)) \) is the corresponding radiation damping coefficient. Eqs
(29) and (30) have been presented, in a different form, by Karatzia & Mylonakis (2012). The complementary coefficients \( w_{ij}^{\mu} \) can be obtained from Eq. (22). The special case of a bilayer soil profile has been considered by Mylonakis (1995) and Mylonakis & Gazetas (1999).

**Generalized parabolic profile**

In case of a soil layer with parabolically varying modulus \( a = \text{arbitrary}, n = \text{arbitrary} \)–Eq. 1, the corresponding coefficients are

\[
S_{hh} = \frac{4\lambda^4}{\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+1}}{2} \Gamma_0 - Q_{11} \cos \left[ \frac{\pi(1+n)}{4} - \theta a \right] + B_{11} \sin \left[ \frac{\pi(1+n)}{4} - \theta a \right] \right\} \tag{32a}
\]

\[
S_{rr} = \frac{8\lambda^4}{3\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+1}}{2} \Gamma_0 - B_{11} \cos \left[ \frac{\pi(1+n)}{4} - \theta a \right] - Q_{11} \sin \left[ \frac{\pi(1+n)}{4} - \theta a \right] \right\} \tag{32b}
\]

\[
S_{hr} = \frac{4\lambda^4}{\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+1}}{2} \Gamma_0 - Q_{11} \cos \left[ \frac{\pi n}{4} - \theta a \right] + B_{11} \sin \left[ \frac{\pi n}{4} - \theta a \right] \right\} \tag{32c}
\]

\[
w_{hh} = \frac{4\lambda^4}{\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+2}}{2} \Gamma_0 - Q_{21} \cos \left[ \frac{\pi(2+n)}{8} - \theta a \right] + B_{21} \sin \left[ \frac{\pi(2+n)}{8} - \theta a \right] \right\} \tag{33a}
\]

\[
w_{rr} = \frac{8\lambda^4}{3\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+2}}{2} \Gamma_0 - B_{21} \cos \left[ \frac{\pi(2+n)}{8} - \theta a \right] - Q_{21} \sin \left[ \frac{\pi(2+n)}{8} - \theta a \right] \right\} \tag{33b}
\]

\[
w_{hr} = \frac{4\lambda^4}{\mu^4} \left[ \frac{3n}{2} \theta^{-n} e^{\theta a} \right] \left\{ \frac{2^{n+2}}{2} \Gamma_0 - Q_{21} \cos \left[ \frac{\pi n}{8} - \theta a \right] + B_{21} \sin \left[ \frac{\pi n}{8} - \theta a \right] \right\} \tag{33c}
\]

where \( \theta = 2d\mu/(1-a) \) and \( \Gamma_0, \Gamma_20, Q_{11}, Q_{21}, B_{11}, B_{21} \) are dimensionless parameters provided in the Appendix. \( n_1 = (1 - \zeta) n, \zeta \text{ being } 0 \) for frequency independent radiation damping as in Berger et al. (1977) and Tabesh and Poulos (2000), and \((-0.4)\) for the power law dependence of \( a_{0.4}^{-1} \) in Eq. 10. \( \lambda_d \) is obtained from Eq. (13) and the corresponding shape parameter \( \mu \) is given by

\[
\mu = \frac{4\lambda_d}{(4+n)(a-1)} \left( \frac{L_d}{d} \right)^{\frac{n+4}{4}} \left[ \frac{a+d}{a} - \left( a + (1-a) \frac{L_d}{d} \right)^{\frac{n+4}{4}} \right] \tag{34}
\]
The special cases of a soil profile whose Young’s modulus increases linearly with depth \( n = 1 \) and one having zero modulus at the soil surface \( a = 0, n \neq 0 \) lead to simpler expressions which are provided in the Supplemental Data File.

**Generalized exponential profile**

For the variation in Young’s modulus in Eq. (6) (Fig. 2b), the following closed-form expressions for the pile stiffness and damping were obtained

\[
S_{hh} = \frac{k_e}{E_p I_p} \left\{ \frac{3}{4\mu^4} + \frac{d (b-1) \left[ (q + 3d\mu)^2 + 3d^2\mu^2 \right]}{\mu^3 \left( q + 2d\mu \right) \left[ (q + 2d\mu)^2 + (2d\mu)^2 \right]} \right\} \quad (35a)
\]

\[
S_{rr} = \frac{k_e}{3E_p I_p} \left\{ \frac{2b (2d\mu)^3 + q \left[ (q + 3d\mu)^2 + 7d^2\mu^2 \right]}{4\mu^4 \left( q + 2d\mu \right) \left[ (q + 2d\mu)^2 + (2d\mu)^2 \right]} \right\} \quad (35b)
\]

\[
S_{hr} = \frac{k_e}{E_p I_p} \left\{ \frac{b (2d\mu)^3 (q + 4d\mu) + q \left[ (q + 3d\mu)^2 + 3d^2\mu^2 \right]}{4\mu^4 \left( q + 2d\mu \right) \left[ (q + 2d\mu)^2 + (2d\mu)^2 \right]} \right\} \quad (35c)
\]

\[
w_{hh} = \frac{\lambda_{ad}^2 \left[ 2A_0 + J_1 + J_2 \right]}{\mu^4 \left( 1 + S_{hh} \right)} \left[ b + (1-b)(1-e^{-q}) \right]^{n_2} \quad (36a)
\]

\[
w_{rr} = \frac{\lambda_{ad}^2 \left[ 2A_0 + J_1 - J_3 \right]}{3\mu^4 \left( 1 + S_{rr} \right)} \left[ b + (1-b)(1-e^{-q}) \right]^{n_2} \quad (36b)
\]

\[
w_{hr} = \frac{\lambda_{ad}^2 \left[ 2A_0 + J_1 - J_3 \right]}{2\mu^4 \left( 1 + S_{hr} \right)} \left[ b + (1-b)(1-e^{-q}) \right]^{n_2} \quad (36c)
\]

where dimensionless parameters \( A_0, J_1, J_2 \) and \( J_3 \) are defined in the Appendix. \( n_2 = (1-\zeta)/2, \zeta \) having the same meaning as before.

Shape parameter \( \mu \) is given by

\[
\mu = \frac{4d\lambda_{ad}}{3qL_a \left[ b + (1-b)(1-e^{-q}) \right]} \left\{ 3b^{1/4} - \left( \frac{1}{b-1} \right)^{3/4} H_{\rho_1} + \left[ 1 + (b-1)e^{-q/\beta} \right]^{1/4} \left( \frac{q/\beta}{(b-1)H_{\rho_2} - 3} \right) \right\} \quad (37)
\]
where $H_{p1}$ and $H_{p2}$ are special functions provided in the Appendix.

The variations of $S_{ij}$ and $w_{rij}$ with the inhomogeneity parameters $a$ and $b$ obtained from Eqs (32), (33), (35) and (36) are depicted in Figs. 8 and 9. In the limit case where $a = b = 1$, the stiffness curves approach the values $S_{hh} = 3$, $S_{rr} = \frac{1}{3}$ and $S_{hr} = 1$ corresponding to homogeneous soil conditions. Likewise, the radiation damping curves approach the values $w'_{hh} = \frac{3}{4}$, $w'_{rr} = \frac{1}{4}$ and $w'_{hr} = \frac{1}{2}$.

With reference to a generalized parabolic profile, Eqs (32) and (33) are presented graphically in Fig. 8 for three different inhomogeneity exponents ($n = \frac{1}{4}$, $\frac{1}{2}$, 1) and pile-soil stiffness contrasts ($E_{p}/E_{sd} = 10^3$, $10^4$, $10^5$). The following noteworthy trends are evident: First, the stiffness coefficients $S_{ij}$ invariably decrease with decreasing inhomogeneity parameter $a$ and increasing $n$, being minimum for $n = 1$ (linear variation of Young’s modulus with depth) and maximum for $n = 0$ (homogeneous soil conditions). Second, the ratio $E_{p}/E_{sd}$ has minor effect on their values. Third, the rocking stiffness coefficient exhibits the smallest variation with the inhomogeneity parameters $a$ and $n$ over the other two coefficients. Similar observations can be made for the radiation damping coefficients $w'_{ij}$, an exception being that the influence of ratio $E_{p}/E_{sd}$ seems to be more important than in the stiffness terms.

The impedance coefficients of a pile embedded in a soil profile with exponentially varying stiffness are illustrated in Fig. 9. In this case, Eqs (35) and (36) are plotted considering three different inhomogeneity parameters ($q = \frac{1}{4}$, $\frac{1}{2}$, 1) and three pile-soil stiffness ratios ($E_{p}/E_{sd} = 10^3$, $10^4$, $10^5$). It is observed that the stiffness coefficients $S_{ij}$ tend to decrease with decreasing values of $b$ and $q$, the trend being more pronounced in the swaying mode. With respect to pile-soil stiffness contrast, stiffness coefficients increase with $E_{p}/E_{sd}$. On the other hand, coefficients $w'_{ij}$ invariably increase with decreasing $b$, $q$ and $E_{p}/E_{sd}$. The results of Figs. 8 and 9 can be used in practical applications, as they cover a wide set of cases without having to numerically evaluate Eqs (32), (33), (35) and (36).
The variation with pile-soil stiffness contrast of coefficients $K_{hh}$, $K_{rr}$ and $K_{hr}$ obtained from the proposed formulation is plotted in Fig. 10 for a linear and a parabolic soil profile, $n=1$, $a=0$ and $n=\frac{1}{2}$, $b=0$, respectively. In the same plot, results from available solutions from the literature are shown for comparison. The stiffness coefficients are normalized with respect to $E_{sd}d^l$, the value of the exponent $l$ being 1, 2 or 3 depending on the oscillation mode. The accord between the proposed analytical solution and the empirical formulas is satisfactory.

A comparison of the damping coefficients obtained from the proposed closed-form solution with those from the empirical solutions of Gazetas (1991) and Syngros (2004) is provided in Fig. 11 for linear soil stiffness variation with depth. Damping coefficients are plotted against dimensionless frequency $\omega_0d (= \omega_0d/V_{sd})$ corresponding to a depth of one pile diameter. The analytical solution compares favorably with the empirical solutions. Also plotted in Fig. 11 are results obtained by means of Eq. (20), based on different formulas for the radiation damping coefficient $c_r$.

**APPLICATION EXAMPLE**

Gazetas and Dobry (1984) presented an illustrative example of a floating pile embedded in a realistic multi-layer soil profile. An almost identical soil stratification is depicted in Fig.12, and is typical of those existing in the San Francisco Bay Area. The soil deposit resting on bedrock has ~60 m depth and consists of seven main layers, whose composition varies from sandy fill at the surface, to stiff and very stiff clays at depth. A 1.4m diameter concrete-filled steel-pipe pile of 0.085 m pipe thickness, embedded in the upper 34 m of the soil stratum is studied. The pile is subjected to lateral dynamic loading with frequency $f$ ranging from 0 to 22 Hz.

The Young’s modulus of an equivalent solid homogeneous pile having the same flexural stiffness $E_pI_p$ as the actual pile is
\[ \tilde{E}_p = E_s \left[ 1 - \left( \frac{1 - 2r_m}{d} \right)^4 \left( 1 - \frac{E_s}{E_{sd}} \right) \right] = 2.5 \cdot 10^8 \left[ 1 - \left( \frac{1 - 2 \cdot 0.085}{1.4} \right)^4 \left( 1 - \frac{2.5 \cdot 10^8}{2.5 \cdot 10^8} \right) \right] = 1.15 \cdot 10^8 \text{ kPa} \ (38) \]

**Step 1:** The active pile length should be determined considering the soil inhomogeneity. As a first approximation, the solution corresponding to linear inhomogeneity with depth \((n = 1)\) will be utilized. Thus, \(L_a\) is computed by means of Eq. (26) selecting the parameters for a linear profile (Table 2), with tolerance \(e_{tol} = 10^{-2}\), \(E_p/E_{sd} = 1.15 \times 10^8/1.32 \times 10^5 = 870\), to get the estimate \(L_a = 10.4\) m \((-7d)\). This suggests that the first two layers, the thick sandy fill and the normally consolidated San Francisco Bay Mud, mainly contribute to the lateral response of pile. Therefore, the stiffness and damping coefficients are obtained using Eqs (29)-(30) considering the contribution of the upper two soil layers, with each layer having constant Young’s modulus, i.e., \(E_{s1} = 132\) MPa and \(E_{s2} = 86\) MPa, respectively. Accordingly, the pile-soil stiffness ratio \(E_p/E_{sd}\) required for computing \(L_a\) is 870. Remarkably, the resulting active length is half of that predicted in the original example based on dynamic considerations.

**Step 2:** The Winkler constant for each layer is obtained by means of Eqs (23) and (25) selecting the parameters for homogeneous profile (Table 1), to get \(\delta = 1.35\) as an average value in the first two layers.

**Step 3:** The Winkler parameters corresponding to the surface upper and the underlying layer are obtained by applying Eq (13), to be found \(\lambda_1 = 0.213\) m\(^{-1}\) and \(\lambda_2 = 0.191\) m\(^{-1}\), respectively. Accordingly, the shape parameter (Eq 31) attains the anticipated average value

\[ \mu = \frac{1}{10.4} \left[ 4.2 \cdot 0.213 + (10.4 - 4.2) \cdot 0.191 \right] = 0.2 \text{ m}^4 \]  

(39)

**Step 4:** The stiffness coefficients \(S_{ii}\) are computed by evaluating Eqs (29a-c) as follows

\[ S_{hh} = \left( \frac{0.213}{0.2} \right)^4 \left\{ -e^{-20.2z} \left[ 2 + \cos \left( 2 \cdot 0.2 \cdot z \right) + \sin \left( 2 \cdot 0.2 \cdot z \right) \right] \right\}_{0}^{4.2} + \]

\[ + \left( \frac{0.191}{0.2} \right)^4 \left\{ -e^{-20.2z} \left[ 2 + \cos \left( 2 \cdot 0.2 \cdot z \right) + \sin \left( 2 \cdot 0.2 \cdot z \right) \right] \right\}_{4.2}^{10.4} = 3.61 \]  

(40a)
\[ S_{rr} = \left( \frac{0.213}{2} \right)^4 \left\{ -2 + \cos(2 \cdot 0.2 \cdot z) - \sin(2 \cdot 0.2 \cdot z) \right\}_0^{4.2} + \]

\[ + \left( \frac{0.191}{2} \right)^4 \left\{ -2 + \cos(2 \cdot 0.2 \cdot z) - \sin(2 \cdot 0.2 \cdot z) \right\}_{4.2}^{10.4} = 0.33 \]  

\[ S_{hr} = \left( \frac{0.213}{2} \right)^4 \left\{ 1 + \sin(2 \cdot 0.2 \cdot z) \right\}_0^{4.2} + \]

\[ + \left( \frac{0.191}{2} \right)^4 \left\{ 1 + \sin(2 \cdot 0.2 \cdot z) \right\}_{4.2}^{10.4} = 1.12 \]  

where the subscripts and superscripts following the curly braces denote difference between values at two elevations.

**Step 5:** By substituting the predicted stiffness coefficients \( S_{ij} \) to Eqs (18a-c) yields the stiffness values \( K_{hh} = 0.8 \times 10^6 \) kN/m, \( K_{rr} = 8.7 \times 10^6 \) kNm and \( K_{hr} = 1.8 \times 10^6 \) kN. \( K_{hh} \) deviates by a mere 10% from the finite-element result reported by Gazetas and Dobry (1984).

**Step 6:** It is straightforward to obtain the dimensionless weight factors \( w_P^{ij} \) via Eq. (22), i.e., \( w_P^{hh} = 0.22, w_P^{rr} = 0.75, w_P^{hr} = 0.47 \).

**Step 7:** As for the radiation damping coefficient \( \beta_r \), Eqs. (10) and (21) are utilized, keeping in mind that the properties are constant within each layer. In the first layer, using \( V_s/V_c = 0.61 \) corresponding to \( \nu = 0.25 \), Eq. (10) yields

\[ c_{r1} = 1.4 \cdot \pi \cdot 1.85 \cdot 169 \cdot (0.25 + 0.8 \cdot 0.61^{-1}) \cdot (2 \cdot \pi \cdot f \cdot 14/169)^{-0.4} \approx 7000 \cdot f^{-0.4} \text{ (kPa} \cdot \text{s)} \]  

(41a)

For the second layer, using \( V_s/V_c = 0.5 \), Eq. (10) provides

\[ c_{r2} = 1.4 \cdot \pi \cdot 1.7 \cdot 130 \cdot (0.25 + 0.8 \cdot 0.5^{-1}) \cdot (2 \cdot \pi \cdot f \cdot 14/130)^{-0.4} \approx 5300 \cdot f^{-0.4} \text{ (kPa} \cdot \text{s)} \]  

(41b)

Since \( k_1 = 1.35 \times 1.32 \times 10^5 = 1.8 \times 10^5 \) kPa and \( k_2 = 1.35 \times 0.86 \times 10^5 = 1.2 \times 10^5 \) kPa, Eq.(21) yields

\[ \beta_{r1} = \frac{2 \cdot \pi \cdot f}{2 \cdot 1.8 \cdot 10^3} \cdot 7000 \cdot f^{-0.4} = 0.122 f^{0.6}, \quad \beta_{r2} = \frac{2 \cdot \pi \cdot f}{2 \cdot 1.2 \cdot 10^3} \cdot 5300 \cdot f^{-0.4} = 0.139 f^{0.6} \]  

(42a,b)

**Step 8:** In the same vein and using \( \beta_{rd} = \beta_{r1} \), damping coefficients \( w_P^{ij} \) (Eq. 30) are estimated as \( w_P^{hh} = 0.79, w_P^{hr} = 0.55, w_P^{rr} = 0.27 \).

**Step 9:** Applying Eq. (20) leads to the following expressions
For simplicity, a fixed value $\beta_s = 0.04$ is adopted for the soil material damping pertaining to the sand material in the upper soil layer. The damping coefficients are illustrated in Fig.13.

**Alternative Solution for Linear Profile**

The same problem may be solved by replacing the actual multi-layer soil profile with an equivalent idealized linear profile. Although this is not essential in the present case (where adequate information for the subsoil is available) the example is solved on the basis of this assumption to demonstrate the applicability of the proposed method and facilitate understanding of the various steps.

Without loss of accuracy, the variation of Young’s modulus within the actual soil deposit can be described by the linear function of depth obtained using linear regression, (Fig.12),

$$E_s(z) = 85.6 (0.85 + 0.11z) \text{ MPa} \quad (44)$$

Note that performing the regression within a shallower range, say within the upper one third of the pile, corresponding to the active length, does not significantly alter the results. To determine the impedance at the pile head, one may utilize the expressions for stiffness and damping coefficients pertaining to the generalized parabolic profile ($a\neq0$, $n\neq0$).

**Step 1:** According to the proposed method, the inhomogeneity parameters $a$ and $n$, and the reference Young’s modulus at depth of one pile diameter are first evaluated at $E_{sd} = 85.6$ MPa, $a = E_{sd}/E_{sd} \approx 0.85$, $n = 1$, resulting from matching Eqs (1) and (44).

**Step 2:** Having determined the ratio $E_p/E_{sd} = 1.15 \times 10^8/0.856 \times 10^5 = 1.34 \times 10^3$, $L_a$ is given by Eq. (26) and Table 2, considering the same parameters as before (assuming tolerance $\varepsilon_{tol} = 10^{-2}$), to get $L_a = 11 \text{ m} \approx (8d)$. 

$$\beta_{hh} = 0.22 \cdot 0.02 + (1 - 0.22) \cdot 0.04 + 0.79 \cdot 0.122 \cdot f^{0.6} = 0.036 + 0.096 \cdot f^{0.6} \quad (43a)$$

$$\beta_{hr} = 0.47 \cdot 0.02 + (1 - 0.47) \cdot 0.04 + 0.55 \cdot 0.122 \cdot f^{0.6} = 0.031 + 0.067 \cdot f^{0.6} \quad (43b)$$

$$\beta_{rr} = 0.75 \cdot 0.02 + (1 - 0.75) \cdot 0.04 + 0.27 \cdot 0.122 \cdot f^{0.6} = 0.025 + 0.033 \cdot f^{0.6} \quad (43c)$$

For simplicity, a fixed value $\beta_s = 0.04$ is adopted for the soil material damping pertaining to the sand material in the upper soil layer. The damping coefficients are illustrated in Fig.13.
Step 3: From Eqs (23) and (25) and choosing the values $\gamma_0 = 1.633$ and $n_1 = -0.2$ from Table 551, pertaining to linear soil stiffness variation with depth, fixed head piles and $v = 0.4$, parameter $\delta$ is estimated at 1.74.

Step 4: Using $a = 0.85$, $n = 1$ and $\lambda_d = 0.2$ m$^{-1}$, the shape parameter $\mu$ obtained from Eq (34) is obtained at 0.22 m$^{-1}$.

Step 5: Stiffness coefficients are given by Eqs (32a-c). Parameter $\theta$ is found to be 4.15, while via Eq. 52b and setting $n^* = n = 1$, parameters $\Gamma_{10}$, $\Gamma_{11}$, $B_{11}$ and $Q_{11}$ are estimated to be

\[
\Gamma_{10} = (4.15 \cdot 0.85)e^{-4.15 \cdot 0.85} \left[1+1/(4.15 \cdot 0.85)\right] = 0.13
\]  

\[
\Gamma_{11} = [4.15 \cdot 0.85 \cdot (1+i)]e^{-4.15 \cdot 0.85 \cdot (1+i)} \left[1+1/[4.15 \cdot 0.85 \cdot (1+i)]\right] = -0.162 - 0.045i
\]  

\[
B_{11} = \text{Re}[\Gamma_{11}] = -0.162, \quad Q_{11} = \text{Im}[\Gamma_{11}] = -0.045
\]  

The application of Eqs (32a-c) using the above values yields

\[
S_{hh} = \frac{4 \cdot 0.2^4}{0.22^4} \cdot 2^{-2} \cdot 4.15^{-1} \cdot e^{4.15 \cdot 0.85} \times \left[2 \cdot 0.13 + 0.045 \cdot \cos \left(\pi/2 - 4.15 \cdot 0.85\right) - 0.162 \cdot \sin \left(\pi/2 - 4.15 \cdot 0.85\right)\right] = 2.3
\]  

\[
S_{rr} = \frac{8 \cdot 0.2^4}{3 \cdot 0.22^4} \cdot 2^{-3} \cdot 4.15^{-1} \cdot e^{4.15 \cdot 0.85} \times \left[2 \cdot 0.13 + 0.162 \cdot \cos \left(\pi/2 - 4.15 \cdot 0.85\right) + 0.045 \cdot \sin \left(\pi/2 - 4.15 \cdot 0.85\right)\right] = 0.31
\]  

\[
S_{hr} = \frac{4 \cdot 0.2^4}{0.22^4} \cdot 2^{-5/2} \cdot 4.15^{-1} \cdot e^{4.15 \cdot 0.85} \times \left[2^{1/2} \cdot 0.13 + 0.045 \cdot \cos \left(\pi/4 - 4.15 \cdot 0.85\right) - 0.162 \cdot \sin \left(\pi/4 - 4.15 \cdot 0.85\right)\right] = 0.85
\]

which suggest that soil contributes 2.3, 0.31 and 0.85 times the amount of stiffness provided by the pile element in swaying, rocking and cross swaying-rocking, respectively.

Step 6: Eqs (18a-c) provide the stiffness values $K_{hh} = 0.79 \times 10^6$ kN/m, $K_{rr} = 9.5 \times 10^6$ kNm and $K_{hr} = 2 \times 10^6$ kN. These results are in good agreement with those obtained using the multi-layer actual profile with discrepancies of 1%, 8% and 10%, respectively.

Using the simpler expressions provided in the Supplemental Data File (Eq. S9) yields
\[
S_{hh} = \frac{3 \cdot 0.2^4}{2 \cdot 1.4 \cdot 0.22^5} \left[ 1 + 0.85(2 \cdot 1.4 \cdot 0.22 - 1) \right] = 2.24
\] 
(47a)

\[
S_{rr} = \frac{0.2^4}{3 \cdot 1.4 \cdot 0.22^5} \left[ 1 + 0.85(1.4 \cdot 0.22 - 1) \right] = 0.3
\] 
(47b)

\[
S_{hr} = \frac{0.2^4}{4 \cdot 1.4 \cdot 0.22^5} \left[ 3 + 0.85(4 \cdot 1.4 \cdot 0.22 - 3) \right] = 0.83
\] 
(47c)

which practically coincide with results in Eq. (46) (differences being due to cut-off errors).

**Step 7:** Applying an analogous procedure for the coefficients \( w_{ij} \), using \( n_i = (1 - (-0.4)) \times 1 = 1.4 \), Eqs (33a-c) lead to \( w_{hh}^r = 0.67 \), \( w_{rr}^r = 0.21 \), \( w_{hr}^r = 0.42 \). Eq. (22) provides the coefficients \( w_{ij}^p \), associated with the pile material damping, i.e, \( w_{hh}^p = 0.30 \), \( w_{rr}^p = 0.76 \), \( w_{hr}^p = 0.54 \).

**Step 8:** Subsequently, the dashpot coefficient \( c_r \) (Eq. 10) computed at depth of one pile diameter according to Eq. (21) is estimated to be

\[
c_{rd} = 1.4 \cdot \pi \cdot 1.85 \cdot 129 \cdot (0.25 + 0.8 \cdot 0.5^{-1}) \cdot (2 \pi f \cdot 1.4/129)^{-0.4} \approx 5200 f^{-0.4} \text{ (kPa} \cdot \text{s)}
\] 
(48)

**Step 9:** Considering \( k_d = 1.5 \times 10^5 \) kPa, the radiation damping coefficient is \( \beta_{rd} = 0.11 f^{0.6} \).

**Step 10:** Finally, the expressions for the dimensionless damping coefficients are

\[
\beta_{hh} = 0.034 + 0.074 f^{0.6}, \quad \beta_{hr} = 0.029 + 0.048 f^{0.6}, \quad \beta_{rr} = 0.025 + 0.024 f^{0.6}
\] 
(49a-c)

**Alternative Solution for an Exponential Profile**

As a second alternative, an idealized exponential soil profile is employed.

**Step 1:** It is assumed that \( E_{\infty} = 480 \) MPa, thus \( b = E_{sd}/E_{\infty} = 58/480 \equiv 0.1 \), and \( q = 0.1 \). The stiffness variation with depth \( z \), depicted in Fig.12, is

\[
E(z) = 480 \left[ 0.1 + 0.9 \left(1 - e^{-0.07z} \right) \right] \text{ MPa}
\] 
(50)

**Step 2:** Considering \( E_p/E_{sd} = 1.15 \times 10^8/0.89 \times 10^5 = 1.3 \times 10^3 \), \( L_a \) is obtained by Eq. (26) and Table 2, assuming \( \epsilon_{tol} = 10^{-2} \), at \( L_a = 12 \text{m} \) (~8.5d).
Step 3: From Eqs. (23) and (25) and using the values $\chi = 1.34$ and $n = -0.23$ from Table 1, for an exponential soil profile and a fixed head pile, parameter $\delta$ is estimated at 1.4 (Poisson’s ratio taken equal to 0.4).

Step 4: Using $b = q = 0.1$, and $\lambda_d = 0.19$ m$^{-1}$, the shape parameter $\mu$ (Eq. 37) is 0.23 m$^{-1}$.

Step 5: From Eqs. (35a-c) with $k = 1.4 \times 4.8 \times 10^5 = 6.7 \times 10^5$ kPa, it is straightforward to obtain the stiffness coefficients $S_{hh} = 1.84$, $S_{rr} = 0.30$ and $S_{hr} = 0.77$.

Step 6: Evaluating Eqs. (18a-c) yield the stiffnesses $K_{hh} = 0.75 \times 10^6$ kN/m, $K_{rr} = 9.7 \times 10^6$ kNm and $K_{hr} = 2 \times 10^6$ kN, which are very similar to those obtained above and highlight the insensitivity of the solution to soil stiffness at depth.

Step 7: Using again $n_2 = (1-(-0.4))/2 = 0.7$, parameters $A_0$, $J_1$, $J_2$ and $J_3$ are numerically evaluated using standard mathematical software at $A_0 = 0.34$, $J_1 = 0.066$, $J_2 = 0.288$ and $J_3 = -0.066$. Substituting the above values into Eqs. (36a-c) yields $w_{hh} = 0.55$, $w_{rr} = 0.18$, $w_{hr} = 0.35$, while Eq. (22) yields $w_{hh} = 0.35$, $w_{rr} = 0.77$, $w_{hr} = 0.56$.

Step 8: Evaluating Eq. (10) leads to $c_{rd} \approx 5300 f^{-0.4}$ kPa-s (similar result with linear profile).

Step 9: Considering $k_d = 1.2 \times 10^5$ kPa, the radiation damping coefficient is $\beta_{rd} = 0.14 f^{-0.6}$.

Step 10: Finally, the expressions for the dimensionless damping coefficients are

$$\beta_{hh} = 0.033 + 0.078 f^{0.6}, \quad \beta_{hr} = 0.029 + 0.049 f^{0.6}, \quad \beta_{rr} = 0.025 + 0.025 f^{0.6} \quad (51a-c)$$

CONCLUSIONS

An approximate, practically-oriented analysis procedure was developed for estimating the dynamic stiffness and damping (impedance coefficients) of a laterally-loaded pile in different types of vertically inhomogeneous soil. To this end, a dynamic Winkler model was adopted in conjunction with a virtual-work scheme associated with approximate shape functions for the pile deflection under imposed head displacements and rotations. Two auxiliary models for
determining the moduli of the distributed Winkler springs and dashpots were also outlined.

The main conclusions of the study are:

1. The proposed analytical technique allows closed-form solutions for the pile stiffness and damping at the pile head to be obtained for both bounded and unbounded, layered soil and soil whose stiffness varies smoothly with depth. Results are provided in dimensionless form, which sheds light into the physics of the problem, including the relative contributions to overall stiffness and damping of the pile and soil components. The insight offered by this modular approach is hardly possible with rigorous numerical solutions such as finite elements.

2. Unlike earlier approximate methods, where a limited number of impedance coefficients are determined, this work covers all six impedance coefficients (i.e., $K_{hh}$, $K_{rr}$, $K_{hr}$, $C_{hh}$, $C_{rr}$, $C_{hr}$) in different soil profiles. The method is self-standing and does not involve empirical information. The solutions have been further improved by employing enhanced expressions for various parameters as summarized in the following.

3. A new model was developed for the distributed Winkler radiation damping coefficient based on a 2D plane strain infinitesimal sector idealization. It was found that, contrary to trends suggested by existing formulae, the dashpot coefficient does not tend to zero at high frequencies, but approaches asymptotically the value $c_r = 1.4 \, d \, \pi \, \rho_s \, V_s$. On the other hand, the 2D plane strain stiffness $k$ goes to zero both at low and high frequencies.

4. A new analytical formulation was developed for the distributed Winkler spring coefficient along the pile, extending an earlier 3D elasticity model by the senior author. In homogeneous soil, Winkler modulus $k$ varies between $1–2 \, E_s$ for both fixed- and free-head piles, whereas for inhomogeneous soil, $k \approx 1–2 \, E_{sd}$ for fixed-head and $1.5–3 \, E_{sd}$ for free-head piles.
5. A novel solution (Eqs. 26-27, Table 2) was derived for the active pile length in different soil profiles. The associated correlation coefficients encompass a tolerance parameter ($i_{tol}$) which helps to explain discrepancies in the results reported in the literature. For $E_p/E_{sd}$ values in the range $10^2$ and $10^3$, $L_a$ varies between 5 and $13d$. The largest $L_a$ occurs in homogeneous soil, and the smallest in a linear profile.

6. Results for pile stiffness and damping obtained with the proposed method are in good agreement with available numerical solutions and fitted formulae. Coefficients $S_{ij}$ indicate that in the lateral mode soil contributes to the overall stiffness between 1 and 3 times the stiffness provided by the pile. In the other two modes the soil contribution is much smaller, ranging between 0.4 and 1 in cross swaying-rocking and 0.17 to 0.34 in rocking.

7. The proposed method can be implemented by means of hand calculations or simple computer spreadsheets and, thereby, can be used in routine calculations for designing piles against lateral dynamic loads.

As a final remark, it is noted that nonlinear effects such as those described by $p-y$ curves can be readily incorporated in the solution, via iterative application of the equations of the layered profile until convergence is achieved. Such applications lie beyond the scope of this work.

APPENDIX: PARAMETERS FOR STIFFNESS & DAMPING COEFFICIENTS

In Eqs (32) and (33) parameters $\Gamma_{10}$, $\Gamma_{20}$, $B_{11} = Re[\Gamma_{11}]$, $B_{21} = Re[\Gamma_{21}]$, $Q_{11} = Im[\Gamma_{11}]$, $Q_{21} = Im[\Gamma_{21}]$ are obtained from the generalized Gamma function

$$\Gamma_{op} = \Gamma\left[\frac{n^* + a}{o}, \frac{2da\mu}{1-a} (1+ip)\right], \quad o = 1, 2, \quad p = 0.1$$

(52a)

with $n^*$ being $n$ and $n_1$ for stiffness and damping coefficients, respectively. For $a = 0$, it can be approximated by Stirling’s formula (see Supplemental Data File); for $a > 0.5$ the following approximation applies (Abramowitz & Stegun 1965)
In Eqs (36a-c) parameters $A_0$, $J_1=\text{Im}[A_{-1}]$, $J_2=\text{Re}[A_{-1}]$ and $J_3=\text{Im}[A_1]$ are denoted as

$$A_\nu = \, _2F_1\left[-n_\nu, (1+i t^*) \frac{2d\mu}{q};1+(1+i t^*) \frac{2d\mu}{q};1-b \right]$$

with $A_\nu$ being a hypergeometric function in which the subscript $t^*$ takes the values $-1$, $0$ and $1$.

In Eq. (37) parameters $H_{p1}$ and $H_{p2}$ denote the following hypergeometric functions

$$H_{p1} = \, _2F_1\left(\frac{3}{4}, \frac{3}{4}, \frac{7}{4} ; \frac{1}{1-b} \right), \quad H_{p2} = \, _2F_1\left(1.1 \frac{7}{4} ; e^d \sqrt{1-b} \right)$$

which can be evaluated using standard computer software such as Matlab and Mathematica.

**NOTATION**

The following symbols are used in this paper:

**Latin symbols**

- $A_{t^*}$ = hypergeometric function
- $a_0$ = dimensionless frequency
- $a_{0d}$ = dimensionless frequency at depth $z = d$
- $B_{1j}$, $B_{2j}$ = real part of generalized Gamma functions $\Gamma_{1j}$ and $\Gamma_{2j}$, respectively
- $b$ = dimensionless inhomogeneity parameter for exponential soil profile
- $C_{hh}$, $C_{rr}$, $C_{hr}$, $C_{ij}$ = damping coefficients in swaying, rocking and cross swaying-rocking at pile head
- $c_r$, $c_r(z)$ = Winkler radiation dashpot modulus
- $c_{rd}$ = Winkler radiation dashpot modulus at depth of one pile diameter
- $c_{ri}$ = dashpot modulus of soil layer $i$
- $d$ = pile diameter
- $E_s$, $E_s(z)$ = soil Young’s modulus
- $E_{s0}$, $E_{sd}$, $E_s\infty$ = soil Young’s modulus at soil surface, at depth of one pile diameter, and at infinite depth, respectively
- $E_p$ = pile Young’s modulus
- $E_p I_p$ = pile flexural stiffness
- $E_c$, $E_{st}$ = Young’s modulus of concrete and steel pile, respectively
- $\tilde{E}_p$ = Young’s modulus of an equivalent solid non hollow pile
\( f \) = excitation frequency

\( G_s, G_s(z) \) = soil shear modulus

\( H_0^{(2)}, H_1^{(2)} \) = zero- and first-order Hankel functions of the second kind

\( H_{p1}, H_{p2} \) = hypergeometric functions

\( h_i \) = thickness of soil layer \( i \)

\( i \) = imaginary unit, number of soil layer in multilayered soil (subscript)

\( ij \) = refers to different vibrational modes

\( J_1, J_2 \) = imaginary and real part of hypergeometric function \( A_i \), respectively

\( J_3 \) = imaginary part of hypergeometric function \( A_i \)

\( k, k(z) \) = Winkler spring modulus

\( k_d, k_\infty \) = Winkler spring modulus at depth \( z = d \) and at infinite depth, respectively

\( k_i \) = Winkler spring modulus of soil layer \( i \)

\( K_{hh}, K_{hr}, K_{rr} \) = pile head stiffness coefficients in swaying, rocking and cross swaying-rocking at pile head

\( K''_{ij} \) = contribution to overall head stiffness of pile flexural stiffness

\( L \) = pile length

\( L_a \) = active pile length

\( l \) = exponent 1, 2 or 3 depending on oscillation mode

\( m \) = pile mass per unit length

\( N \) = number of homogeneous layers

\( n \) = dimensionless inhomogeneity exponent for generalized parabolic soil profile

\( n_1, n_2, n^* \) = dimensionless parameters

\( n_b, n_L \) = dimensionless coefficients

\( o, p \) = arguments of generalized Gamma function

\( q \) = dimensionless inhomogeneity exponent for exponential soil profile

\( Q_{11}, Q_{21} \) = imaginary part of generalized Gamma functions \( \Gamma_{11} \) and \( \Gamma_{21} \), respectively

\( S_{ij} \) = dimensionless stiffness coefficient expressing the contribution of the restraining action of soil to the overall head stiffness

\( t \) = time

\( t_w \) = wall thickness of hollow pile

\( t^* \) = argument of hypergeometric function

\( V_c \) = soil compressional wave propagation velocity

\( V_s \) = soil shear wave propagation velocity

\( V_{sd} \) = soil shear wave velocity at depth of one pile diameter

\( V_{La} \) = Lysmer’s analog wave propagation velocity

\( w_{ij}, w_{ij}^* \) = weight factors expressing the contribution of pile material and radiation damping.
